population mortality (LC_{50}) between 6 and 400 ppb total PAH concentration after 96 hrs exposure, with an average of 50 ppb. Hence, concentrations lower than 6 ppb total PAH value should be protective of 97.5% of species and life stages even with exposure periods of days (at least 96 hours). Early life-history stages of fish appear to be more sensitive than older fish stages and invertebrates.

Exceedances of 10, 50 or 400 ppb over a 1 hour timestep (see Table 7.6) were applied to indicate increasing potential for sub-lethal to lethal toxic effects (or low to high), in alignment with the commonly used exposure values for oil spill modelling presented in NOPSEMA (2019).

7.2.3.2 Entrained Hydrocarbons

Entrained hydrocarbons consist of oil droplets that are suspended in the water column and insoluble. As such, insoluble compounds in oil cannot be absorbed from the water column by aquatic organisms, hence are not bioavailable through absorption of compounds from the water. Exposure to these compounds would require routes of uptake other than absorption of soluble compounds. The route of exposure of organisms to whole oil alone include direct contact with tissues of organisms and uptake of oil by direct consumption, with potential for biomagnification through the food chain (NRC, 2003).

The 10-ppb threshold represents the very lowest concentration and corresponds generally with the lowest trigger levels for chronic exposure for entrained hydrocarbons in the ANZECC (2000) water quality guidelines. Due to the requirement for relatively long exposure times (≥ 24 hours) for these concentrations to be significant, they are likely to be more meaningful for juvenile fish, larvae and planktonic organisms that might be entrained (or otherwise moving) within the entrained plumes, or when entrained hydrocarbons adhere to organisms or trapped against a shoreline for periods of several days or more.

Exposure to entrained oil at 10 ppb is not considered to be of significant biological impact and is therefore outside the adverse exposure zone. This exposure zone represents the area contacted by the spill. This area does not define the area of influence as it is considered that the environment will not be affected by the entrained hydrocarbon at this level.

Thresholds of 10 ppb and 100 ppb were applied over a 1 hour time exposure (Table 7.6), to cover the range of thresholds outlined in the ANZECC/ARMCANZ (2000) water quality guidelines, the incremental change for greater potential effect and is per NOPSEMA (2019).

A complicating factor that should be considered when assessing the consequence of dissolved and entrained oil distributions is that there will be some areas where both physically entrained oil droplets and dissolved hydrocarbons co-exist. Higher concentrations of each will tend to occur close to the source where sea conditions can force mixing of relatively unweathered oil into the water column, resulting in more rapid dissolution of soluble compounds.

Table 7.6 Dissolved and entrained hydrocarbon instantaneous exposure thresholds used in this report (in alignment with NOPSEMA, 2019).

	Exposure level	In-water threshold (ppb)	Description
Disolved hydrocarbons	Low	10	Establishes planning area for scientific monitoring based on potential for exceedance of water quality triggers
	Moderate	50	Approximates potential toxic effects, particularly sublethal effects to sensitive species
	High	400	Approximates toxic effects including lethal effects to sensitive species
Entrained hydrocarbons	Low	10	Establishes planning area for scientific monitoring based on potential for exceedance of water quality triggers
	Moderate	100	As appropriate given oil characteristics for informing risk evaluation

7.3 Sensitive Receptors

A range of environmentally sensitive receptors and biological receptors and shorelines were assessed for sea surface exposure, shoreline accumulation and water column exposure as part of the study (see Figure 7.2 to Figure 7.13). Receptor categories (see Table 7.7) include sections of shorelines, which are defined by local government areas (LGAs) and offshore islands, along with submerged reefs, shoals and banks (RSB). All other sensitive receptors were sourced from http://www.environment.gov.au/. Risks of exposure were separately calculated for each sensitive receptor and have been tabulated. Note, AMPs are assumed to extend from sea surface to seabed. While the KEFs and Glomar Shoals RSB were individually assessed at their shallowest depth from the sea surface and therefore, assumed not be impacted by floating oil if they occur >0-10m water depth.

Note that the Australian Exclusive Economic Zone (EEZ) and the Northwest Shelf Integrated Marine and Coastal Regionalisation of Australia (IMCRA) were excluded from tabulated results as the release locations reside within the receptor boundaries and therefore will always record a 100% probability of exposure.

Note that Indonesian shorelines presented in Figure 7.10 were grouped with the highest probability and lowest minimum time presented as ‘Indonesia’ in tabulated results.

Table 7.7 Summary of receptors used to assess surface, shoreline and in-water exposure to hydrocarbons.

8 MODEL SETTINGS

Table 8.1 provides a summary of the oil spill model settings for each scenario. The table also shows the thresholds that were used.

The potential risk of exposure to the surrounding waters and accumulation on shorelines was assessed for three distinct seasons; summer (October to March), winter (May to August) and transitional (April and September). This approach assists with identifying the environmental values and sensitivities that would be at risk of exposure on a seasonal basis.

The simulation lengths for each scenario was carefully selected based on extensive sensitivity testing. During the sensitivity testing process, sample spill simulations were run for longer than intended durations. Upon completion of the spill simulations, the results were carefully assessed to examine the persistence of the hydrocarbon (i.e. whether the maximum evaporative loss has been achieved for the period of time modelled; and whether a substantial volume of hydrocarbons remain in the water column (if any)) in conjunction with the extent of sea surface exposure based on reporting thresholds. Once there was agreement between the two factors (i.e. the final fate of hydrocarbon is accounted for and the full exposure area is identified) the simulation length was deemed appropriate.

Table 8.1 Summary of the oil spill model settings used in this assessment.

Input Parameters	Scenario 1 (Section 9.1)	Scenario 2 (Section 9.2)	Scenario 3 (Section 9.3)	Scenario 4 (Section 9.4)	Scenario 5 (Section 9.5)	Scenario 6 (Section 9.6)

9 MODELLING RESULTS

9.1 Scenario 1: Simulation of a 14-week subsea blowout of crude at the WHP

This scenario examined a 12,779,600 bbl (2,031,794 m^3) subsea release of crude with a decreasing discharge rate over 14 weeks. A total of 300 simulations were run (i.e. 100 spills per season) and each was tracked for 118 days. These are then combined and presented as exposures zones for each season (cumulative of 100 simulations) for the low, moderate and high thresholds.

Sections 9.1.1 presents an overview of the EMBA based on combining the 300 spill simulations and Section 9.1.3 shows the seasonal (or stochastic) analysis, while Section 9.1.2 presents the deterministic analysis results (i.e. a single spill simulation), based on largest volume ashore and longest length of oiled shoreline.

9.1.1 Overview

Figure 9.1 and Figure 9.2 are maps which encompass the full geographic EMBA derived by overlaying the combined results from all 300 spill simulations at both the low and moderate exposure thresholds, respectively.

Figure 9.3 and Figure 9.4 show the annualised extent of floating oil and in-water (entrained and dissolved) exposure as well as shoreline accumulation based on the low and moderate exposure thresholds, respectively, derived from combining the results from all 300 spill simulations.

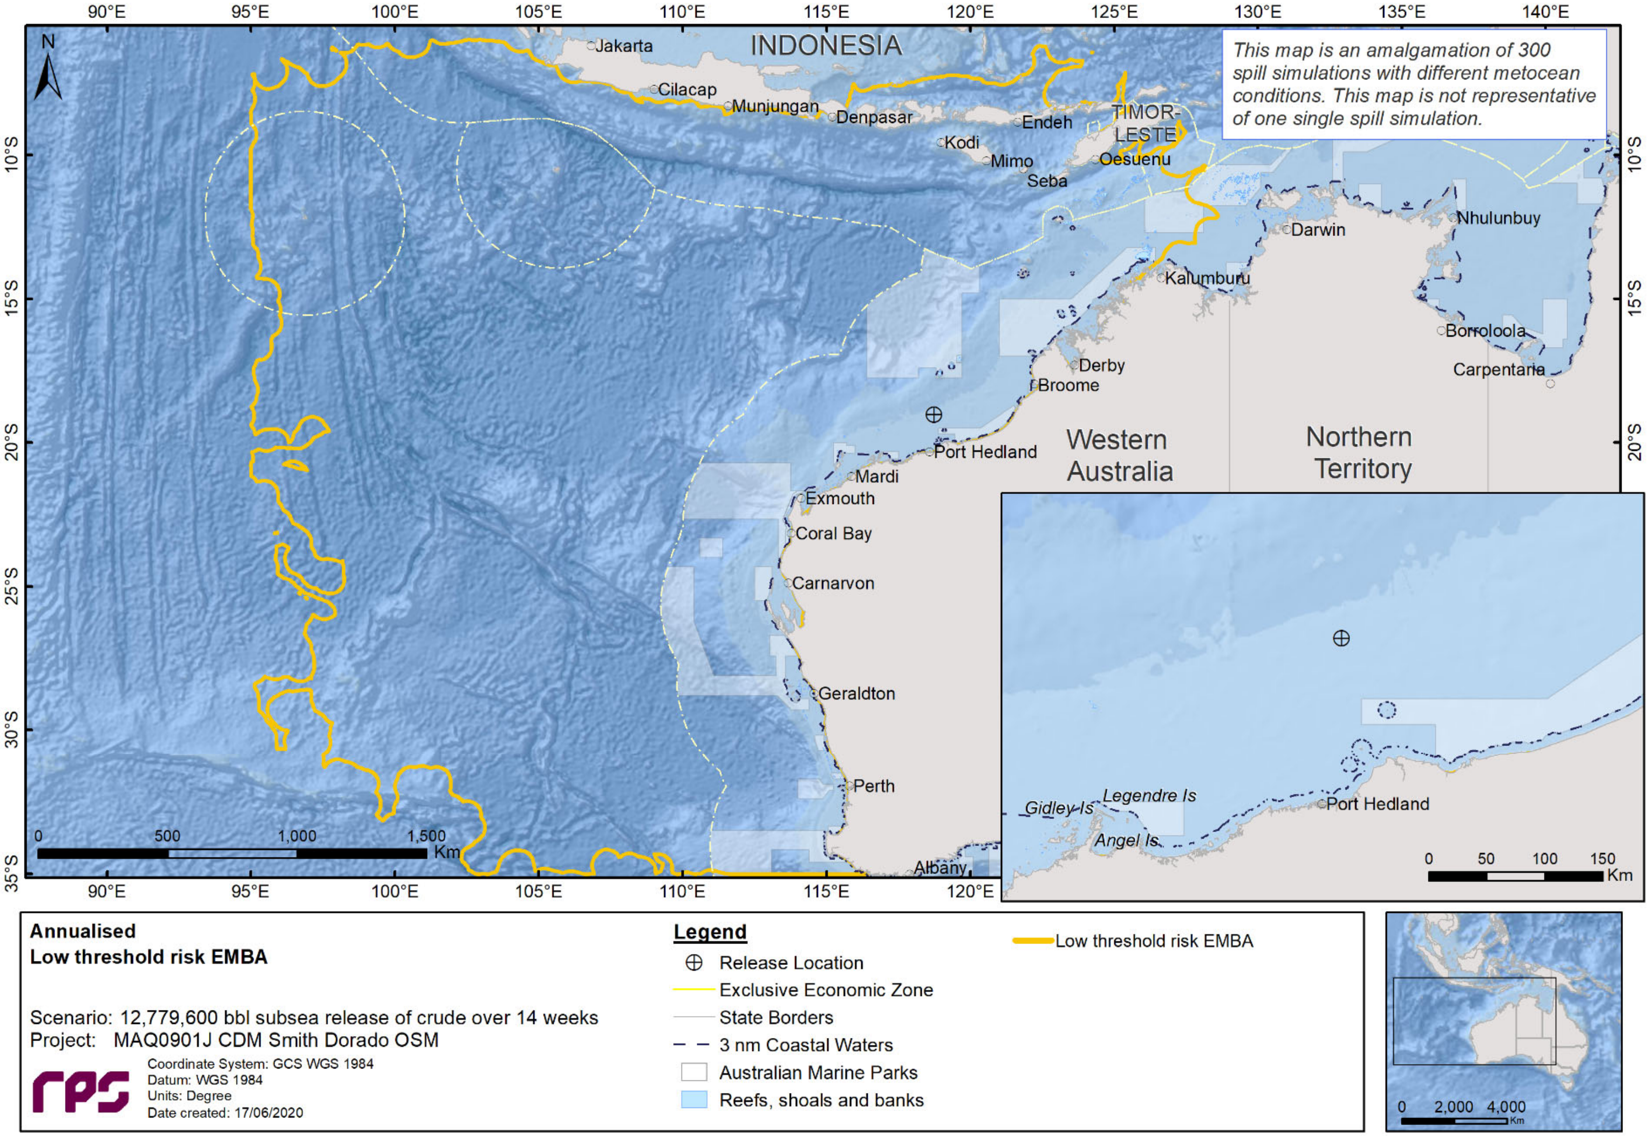

Figure 9.1 Predicted low threshold risk EMBA resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The annualised results were calculated from 300 spill simulations and each was tracked for 118 days.

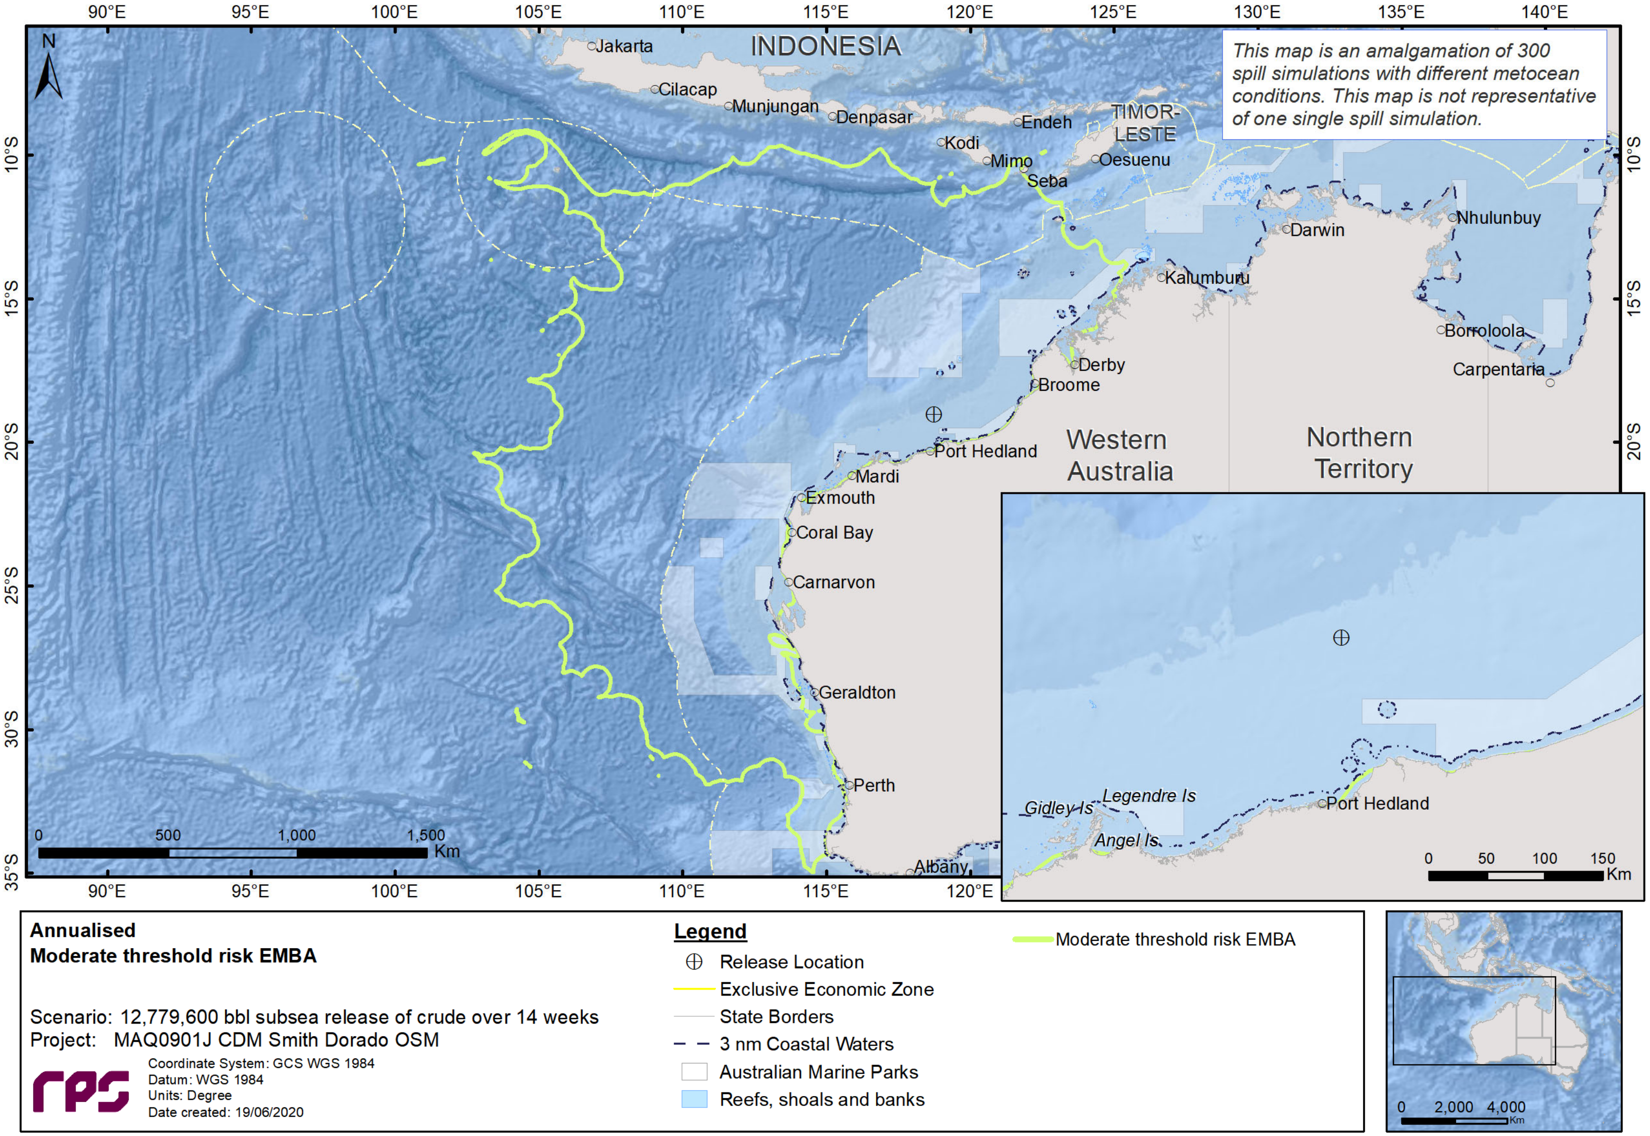

Figure 9.2 Predicted moderate threshold risk EMBA resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The annualised results were calculated from 300 spill simulations and each was tracked for 118 days.

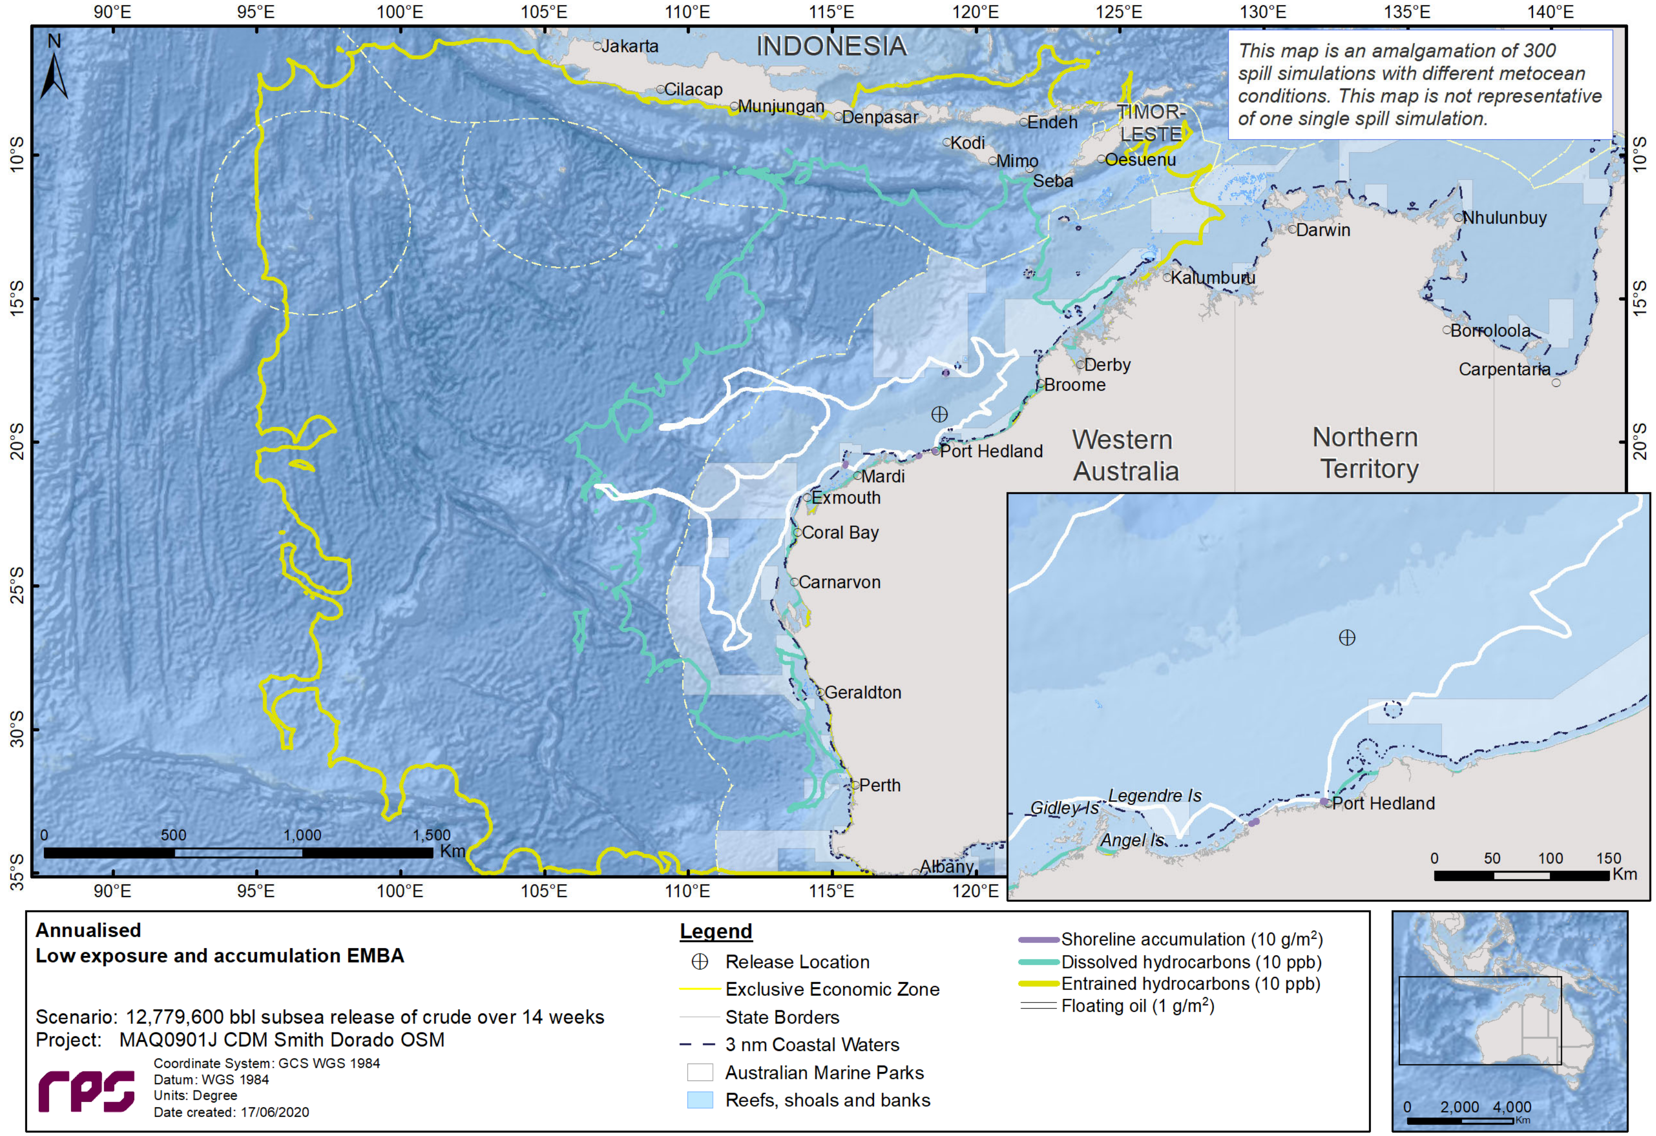

Figure 9.3 Annualised low threshold oil exposure and shoreline accumulation resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The annualised results were calculated from 300 spill simulations and each was tracked for 118 days.

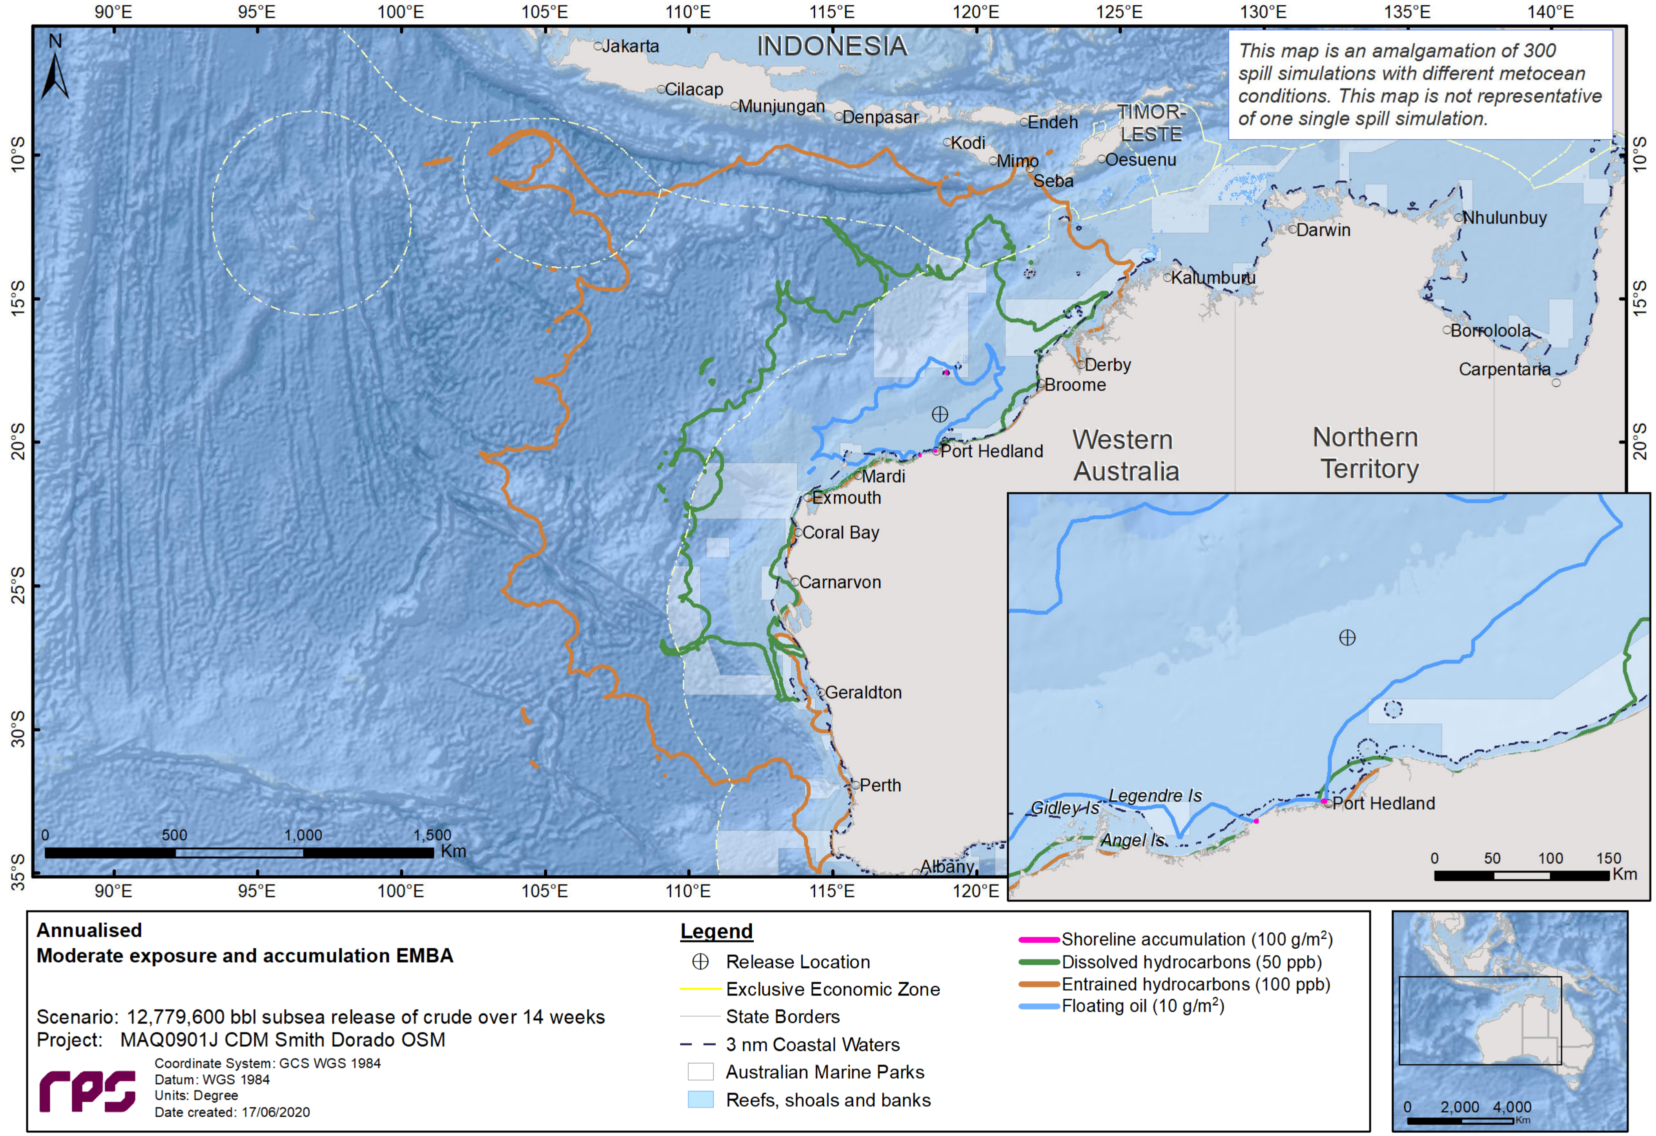

Figure 9.4 **Annualised moderate threshold oil exposure and shoreline accumulation resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP. The annualised results were calculated from 300 spill simulations and each was tracked for 118 days.**

9.1.2 Deterministic Analysis

The stochastic modelling results were assessed and the deterministic runs were identified and presented below based on the following criteria;

a. Largest volume of oil ashore; and

b. Longest length of oiled shoreline.

9.1.2.1 Deterministic Case: Largest volume of oil ashore

The deterministic simulation that recorded the largest volume of oil ashore was identified during transitional conditions as run number 9, which commenced at 7 pm on the 4th of April 2018. The maximum volume ashore was 64.7 m^3, which occurred 3 days after the initial release.

Exposure from floating oil (swept area) and potential oil accumulation over the entire 118 day simulation are presented in Figure 9.5 and Figure 9.6, respectively. Floating oil exposure was predicted to occur northeast and west/southwest from the release location, while oil accumulation occurred at the sensitive receptor (refer Section 7.3) of Port Hedland.

Figure 9.7 displays the time series of the area and length of visible oil (≥1 g/m^2) and actionable floating oil exposure on the sea surface (≥50 g/m^2) and moderate shoreline oil (≥100 g/m^2) over the 118-day simulation.

Figure 9.8 is a time series of the volume on shore at the low (10-100 g/m^2), moderate (100-1,000 g/m^2) and high (≥ 1,000 g/m^2) thresholds.

Figure 9.9 presents the fates and weathering graph for the corresponding simulation. At the conclusion of the simulation period, approximately 1,245,004 m^3 (61%) spilled oil was lost to the atmosphere through evaporation. Approximately 625,213 m^3 (31%) of the crude was predicted to have decayed, while 159,119 m^3 (8%) remained within the water column and 22 m^3 (<0.1%) was predicted to remain on the shoreline.

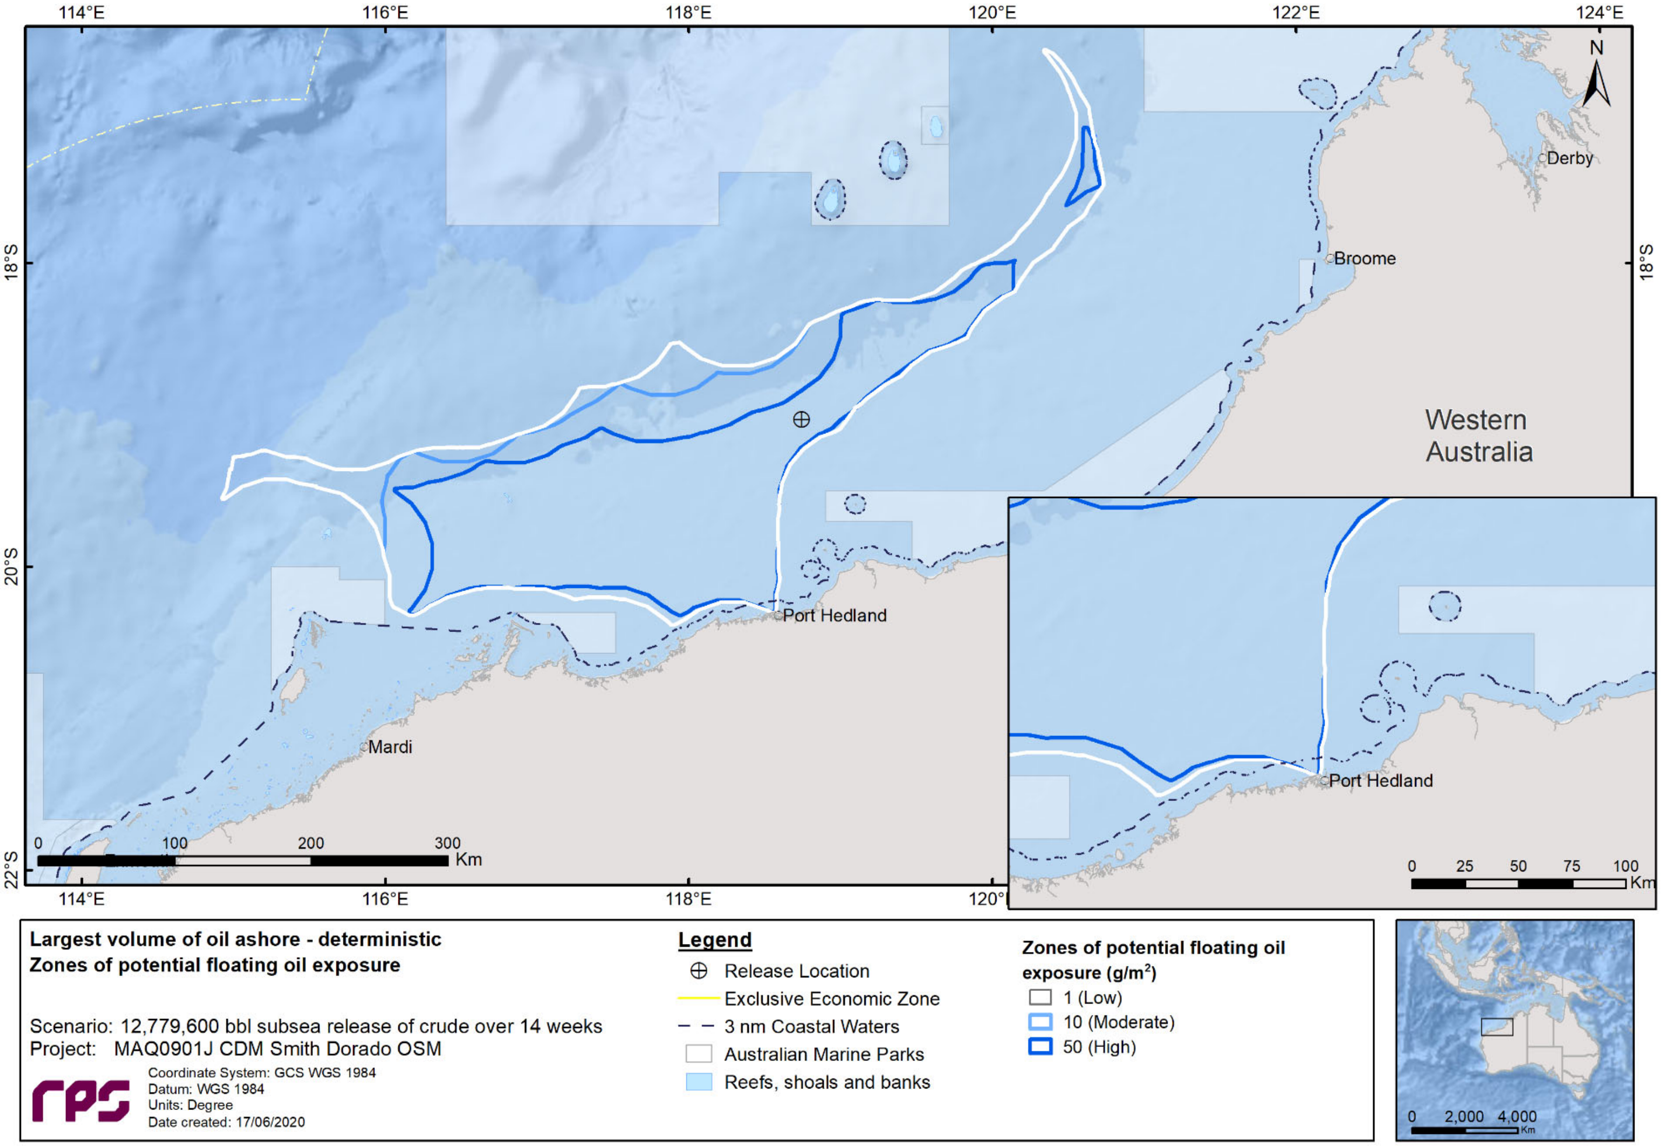

Figure 9.5 Exposure from floating oil (over the 118 day simulation) for the simulation with the largest volume of oil ashore. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, starting 7 pm on the 4th of April 2018.

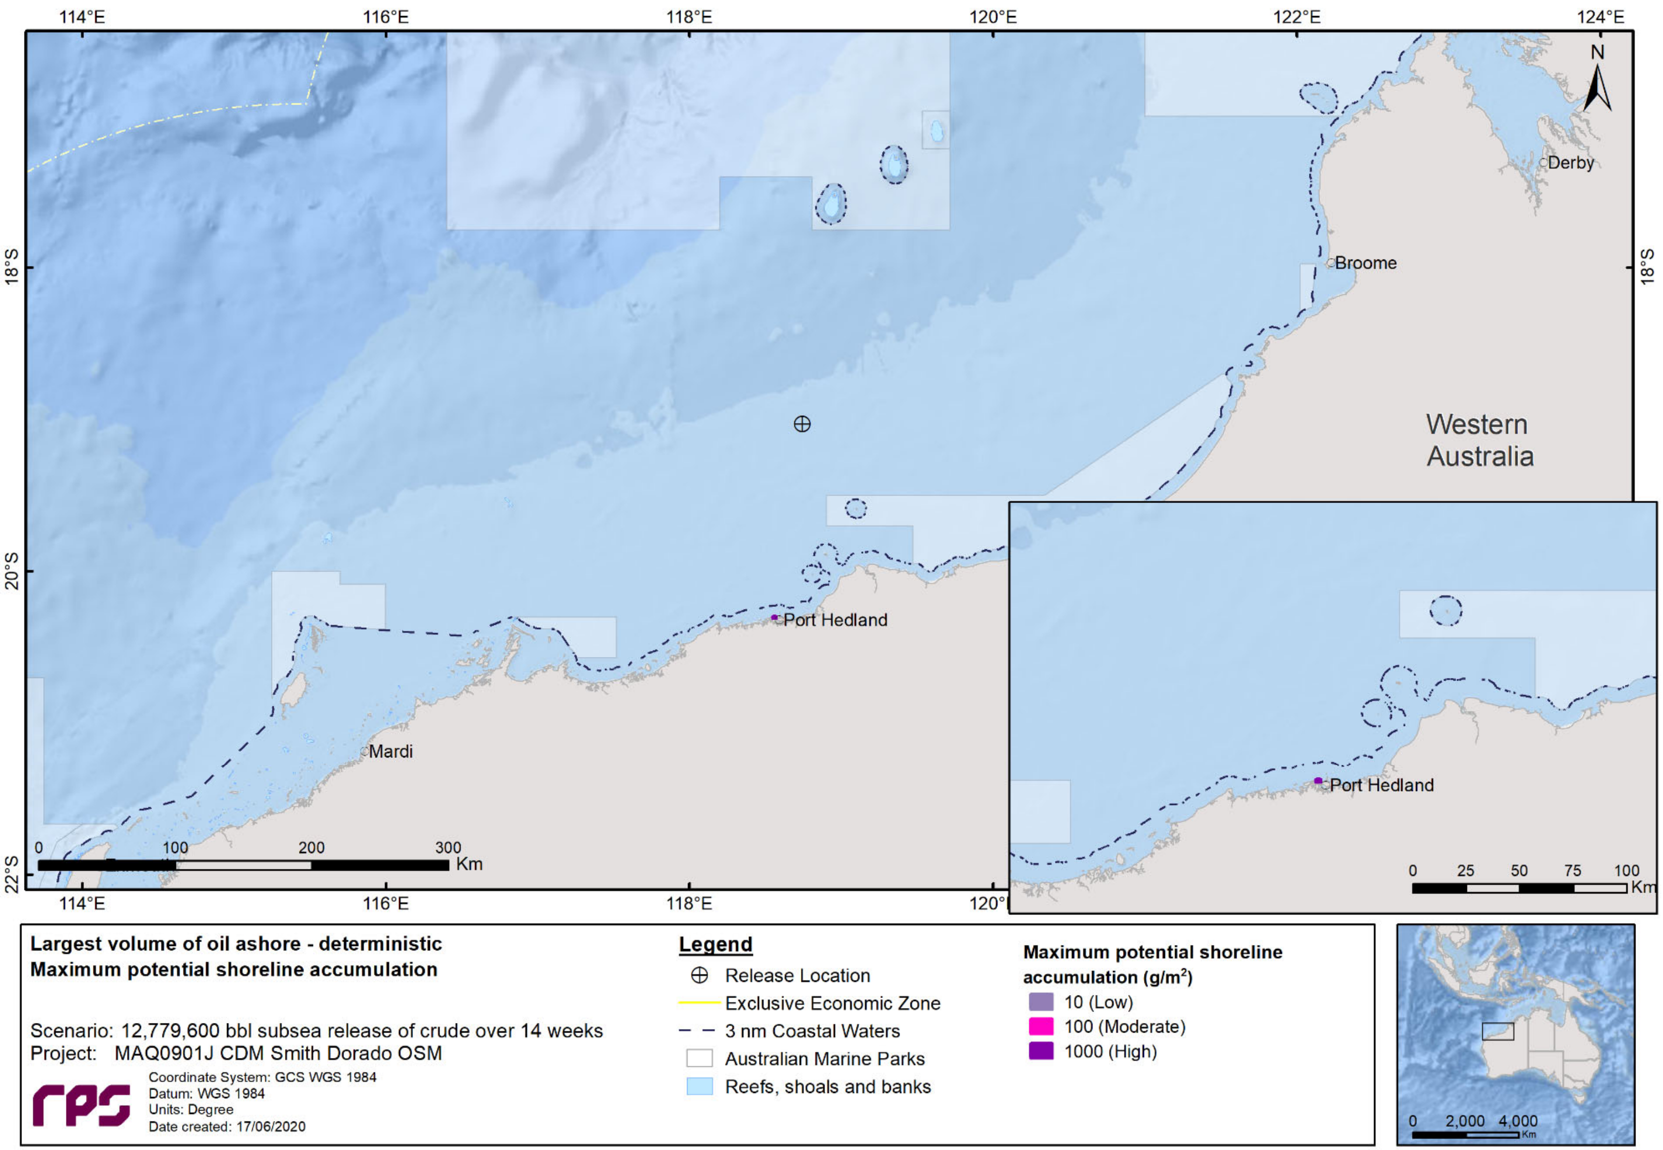

Figure 9.6 Potential shoreline accumulation (over the 118 day simulation) for the simulation with the largest volume of oil ashore. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, starting 7 pm on the 4th of April 2018.

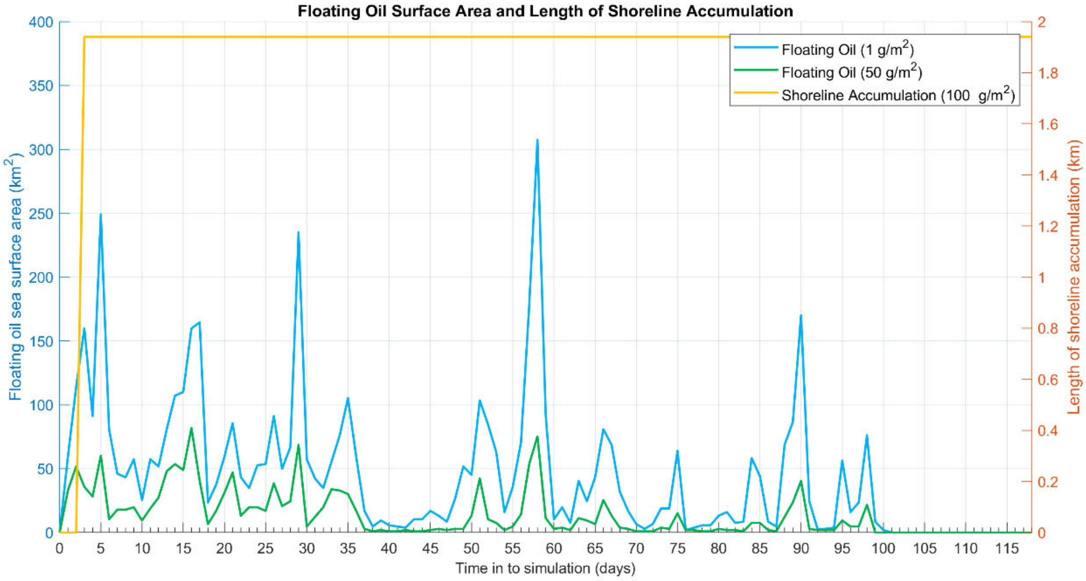

Figure 9.7 **Time series of the area of visible (≥1 g/m²) and actionable floating oil (≥50 g/m²) on the sea surface and length of actionable shoreline oil (≥100 g/m²) for the simulation with the largest volume of oil ashore. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP, tracked for 118 days.**

Figure 9.8 **Time series of volume on shore at the low (10-100 g/m²), moderate (100-1,000 g/m²) and high (≥ 1,000 g/m²) thresholds for the simulation with the largest volume of oil ashore. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP, tracked for 118 days.**

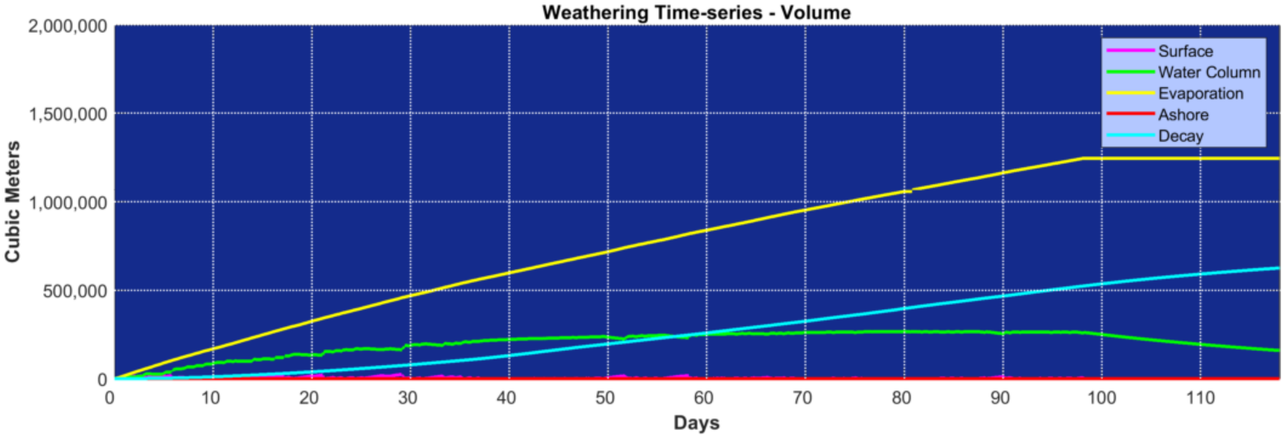

Figure 9.9 Predicted weathering and fates graph for the single spill simulation with the largest volume of oil ashore. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, tracked for 118 days.

9.1.2.2 Deterministic Case: Longest length of oiled shoreline

The deterministic simulation that resulted in the longest length of oiled shoreline above 100 g/m^2 was identified during summer conditions as run number 60, which commenced at 11 pm on the 17th of January 2018.

Exposure from floating oil (swept area) and potential oil accumulation over the entire 118-day simulation are presented in Figure 9.10 and Figure 9.11, respectively. Floating oil exposure was predicted to occur northeast and west/southwest from the release location with oil accumulation occurring at the sensitive shoreline receptors (refer Section 7.3) of Port Hedland, Cunningham Island and Imperieuse Reef.

Figure 9.12 displays the time series of the area and length of visible oil (≥1 g/m^2) and actionable floating oil exposure on the sea surface (≥50 g/m^2) and actionable shoreline oil (≥100 g/m^2) over the 118-day simulation. The maximum area of coverage of visible oil on the sea surface was predicted to occur 46 days after the spill started and covered approximately 559 km^2. While the maximum length of actionable shoreline oiled (above 100 g/m^2) at any given time was 2 km, approximately 80 days into the simulation.

Figure 9.13 is a time series of the volume on shore at the low (10-100 g/m^2), moderate (100-1,000 g/m^2) and high (≥ 1,000 g/m^2) thresholds.

Figure 9.14 presents the fates and weathering graph for the corresponding simulation. At the conclusion of the simulation period, approximately 1,267,855 m^3 (62%) spilled oil was lost to the atmosphere through evaporation. Approximately 597,580 m^3 (29%) of the crude was predicted to have decayed, while 162,903 m^3 (8%) remained within the water column and 15 m^3 (<0.1%) was predicted to remain on the shoreline.

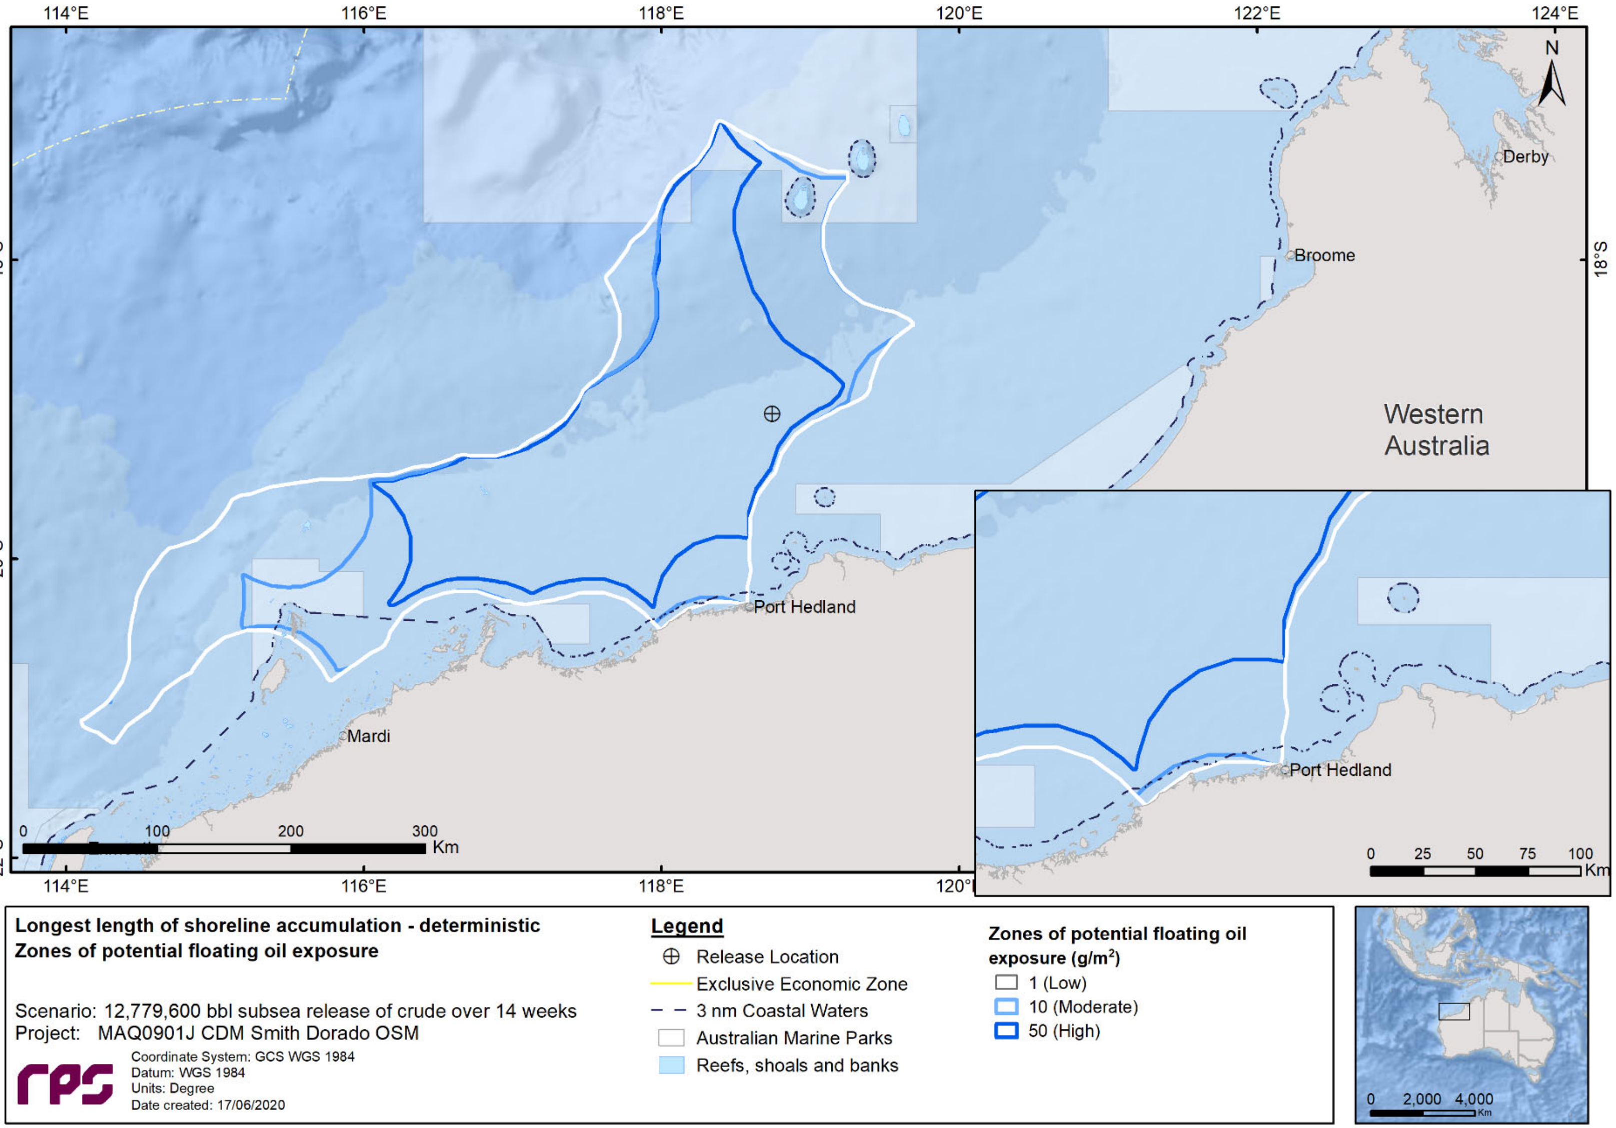

Figure 9.10 Exposure from floating oil (over the 118 day simulation) for the simulation with the longest length of shoreline with accumulation above 100 g/m². Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP, starting 11 pm on the 17th of January 2018.

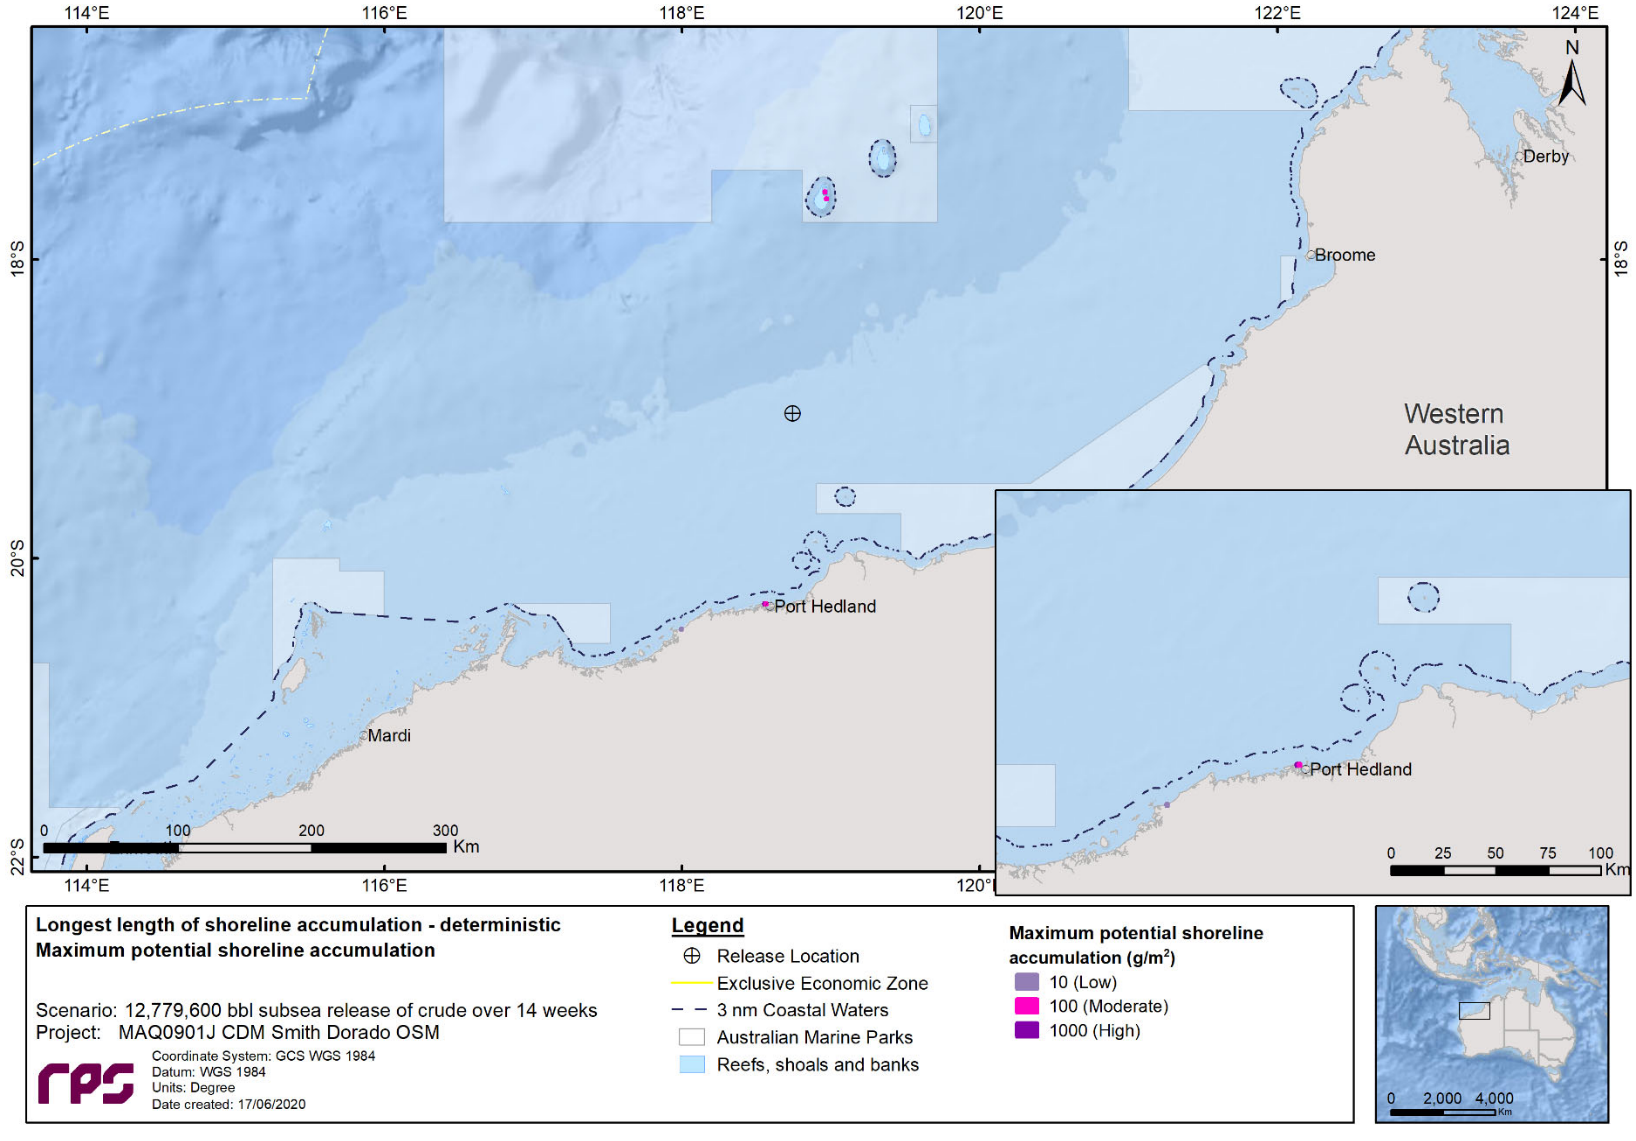

Figure 9.11 **Potential shoreline accumulation (over the 118 day simulation) for the simulation with the longest length of shoreline with accumulation above 100 g/m². Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP, starting 11 pm on the 17th of January 2018.**

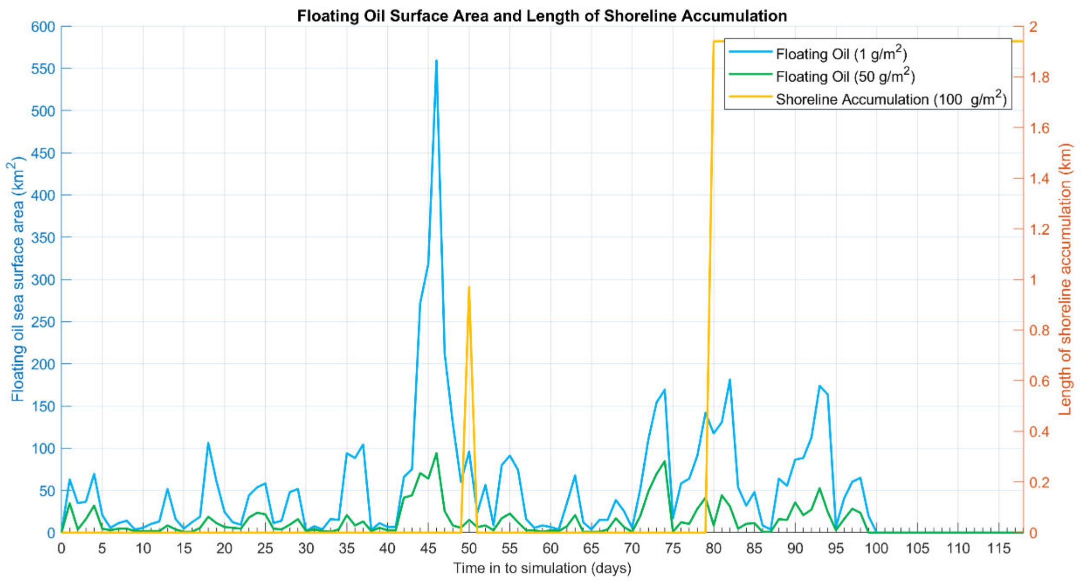

Figure 9.12 Time series of the area of visible (≥1 g/m²) and actionable floating oil (≥50 g/m²) on the sea surface and length of actionable shoreline oil (≥100 g/m²) for the simulation with the longest length of shoreline with accumulation above 100 g/m². Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP, tracked for 118 days.

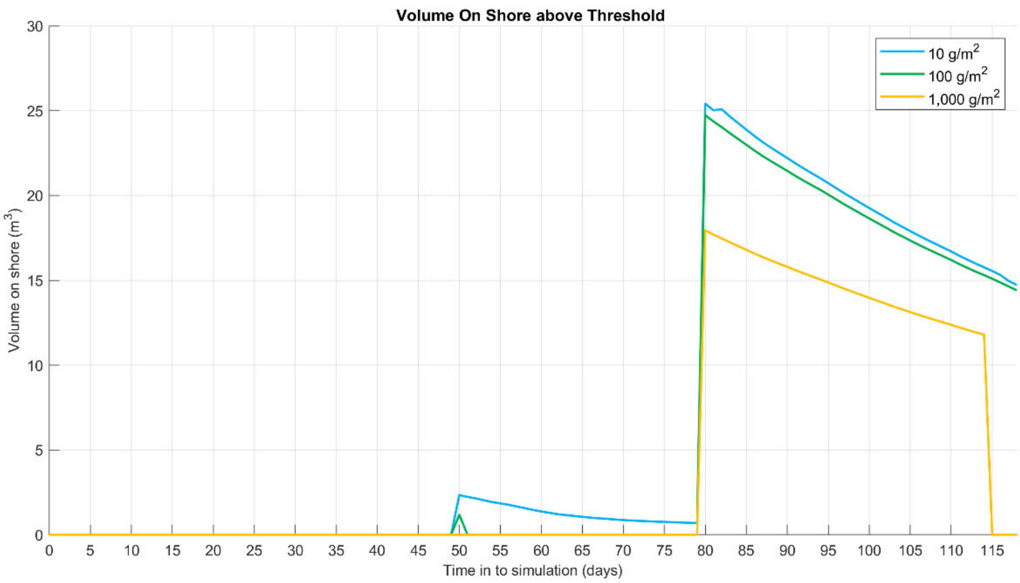

Figure 9.13 Time series of the volume on shore at the low (10-100 g/m²), moderate (100-1,000 g/m²) and high (≥ 1,000 g/m²) thresholds for the simulation with the longest length of shoreline with accumulation above 100 g/m². Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP, tracked for 118 days.

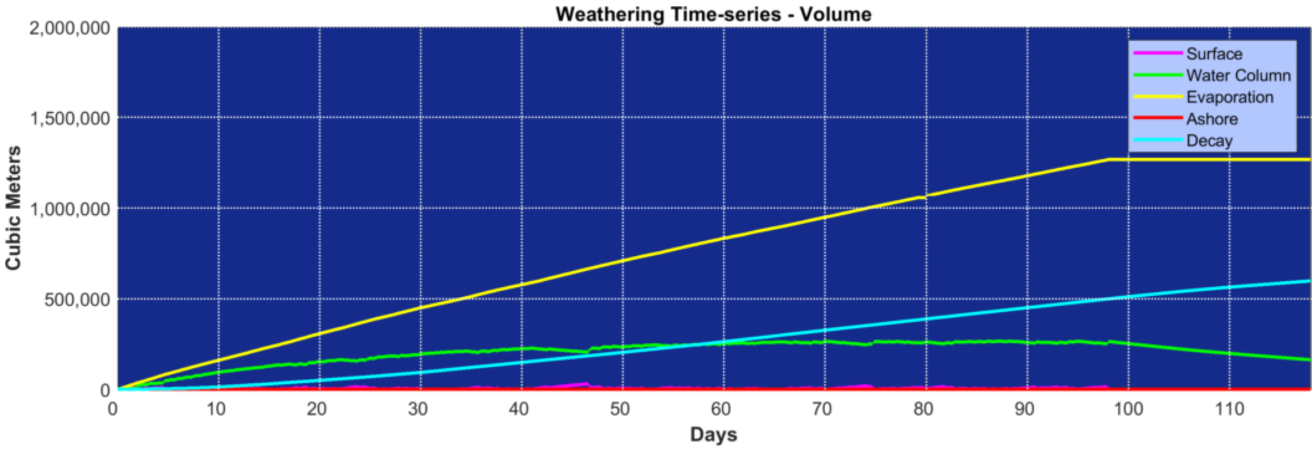

Figure 9.14 Predicted weathering and fates graph for the single spill simulation with the longest length of shoreline with accumulation above 100 g/m^2. Results are based a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, tracked for 118 days, 11 pm on the 17th of January 2018.

9.1.3 Seasonal analysis

9.1.3.1 Floating Oil Exposure

Table 9.1 summarises the maximum distances from the release location to floating oil exposure zones for each season. The maximum distance from the release location to the low (1–10 g/m^2), moderate (10–50 g/m^2) and high (≥ 50 g/m^2) exposure thresholds was 1,278.2 km west-southwest, 528.3 km west-southwest and 304.5 km west-southwest, respectively, all predicted during summer conditions.

Images of floating oil exposure zones are depicted in Figure 9.15, Figure 9.16 and Figure 9.17 for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively.

Table 9.2 to

Table 9.4 summarises the potential for floating oil exposure to individual receptors for each season, based on combining the results of the 100 simulations. Within the predicted exposure zone from the combined season simulations, there are 8 AMPs, 7 during summer and 2 each during transitional and winter conditions. The Montebello AMP recorded the highest probability of exposure to floating oil at 18% during summer conditions. The shortest time for floating oil to reach an AMP was recorded at Argo-Rowley Terrace (7.54 days) during summer conditions.

There are 3 RSBs within the predicted zone of floating oil exposure (at the low threshold), with the highest probability of exposure predicted at Imperieuse Reef during summer conditions (7%). The shortest time before floating oil contacted a RSB receptor was predicted at Tryal Rocks, taking 14.04 days during summer conditions.

Exposure (at the low threshold) was predicted to cross into WA State Waters during every season with probabilities ranging from 1-12%. The minimum time before oil crossed the WA State Waters boundary was 2.83 days recorded for a spill commencing during transitional conditions.

Table 9.1 Maximum distance and direction from the release location to floating oil exposure thresholds. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations per season.

Season	Distance and direction	Exposure from floating oil		
		Low (1-10 g/m^2)	Moderate (10-50 g/m^2)	High (≥50 g/m^2)
Summer	Max. distance from release site (km)	1,278.2	528.3	304.5
	Max distance from release site (km) (99th percentile)	1,050.2	308.1	219.1
	Direction	West-Southwest	West-Southwest	West-Southwest
Transitional	Max. distance from release site (km)	498.8	498.8	305.0
	Max distance from release site (km) (99th percentile)	386.5	326.6	261.3
	Direction	West-Southwest	West-Southwest	West-Southwest
Winter	Max. distance from release site (km)	413.5	413.5	221.7
	Max distance from release site (km) (99th percentile)	298.4	269.5	153.2
	Direction	West	West	Northeast

Table 9.2 Summary of the potential floating oil exposure to individual receptors. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during summer (October to March) conditions. Figure 9.15 Predicted floating oil exposure zones resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

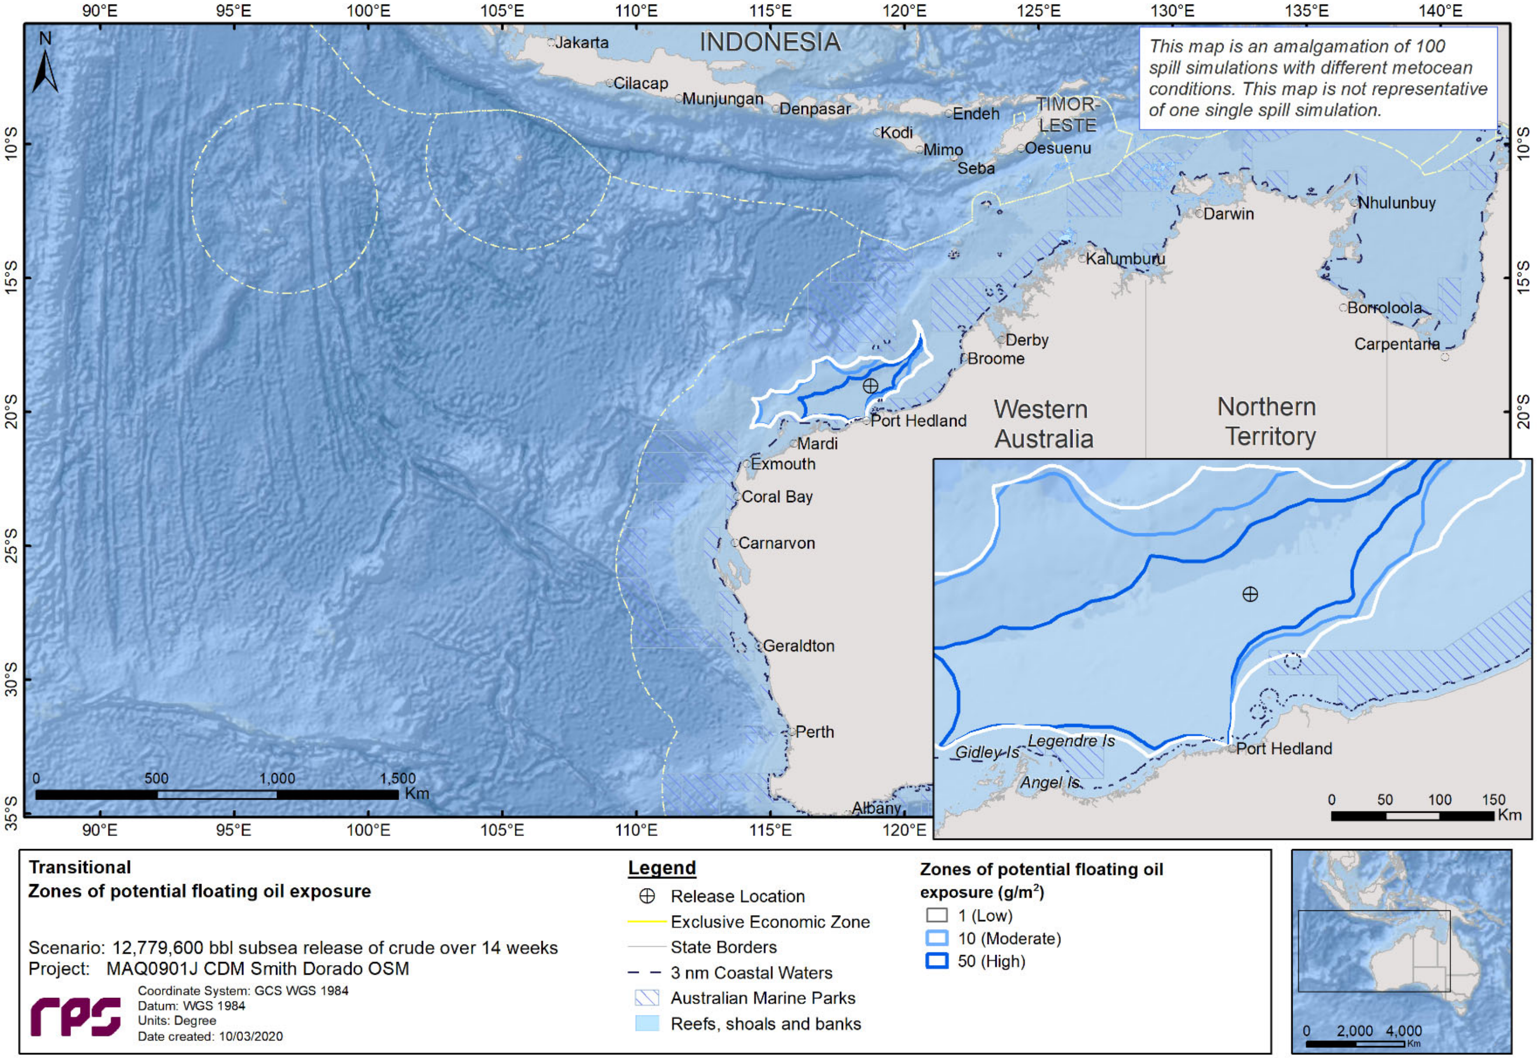

Figure 9.16 Predicted floating oil exposure zones resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

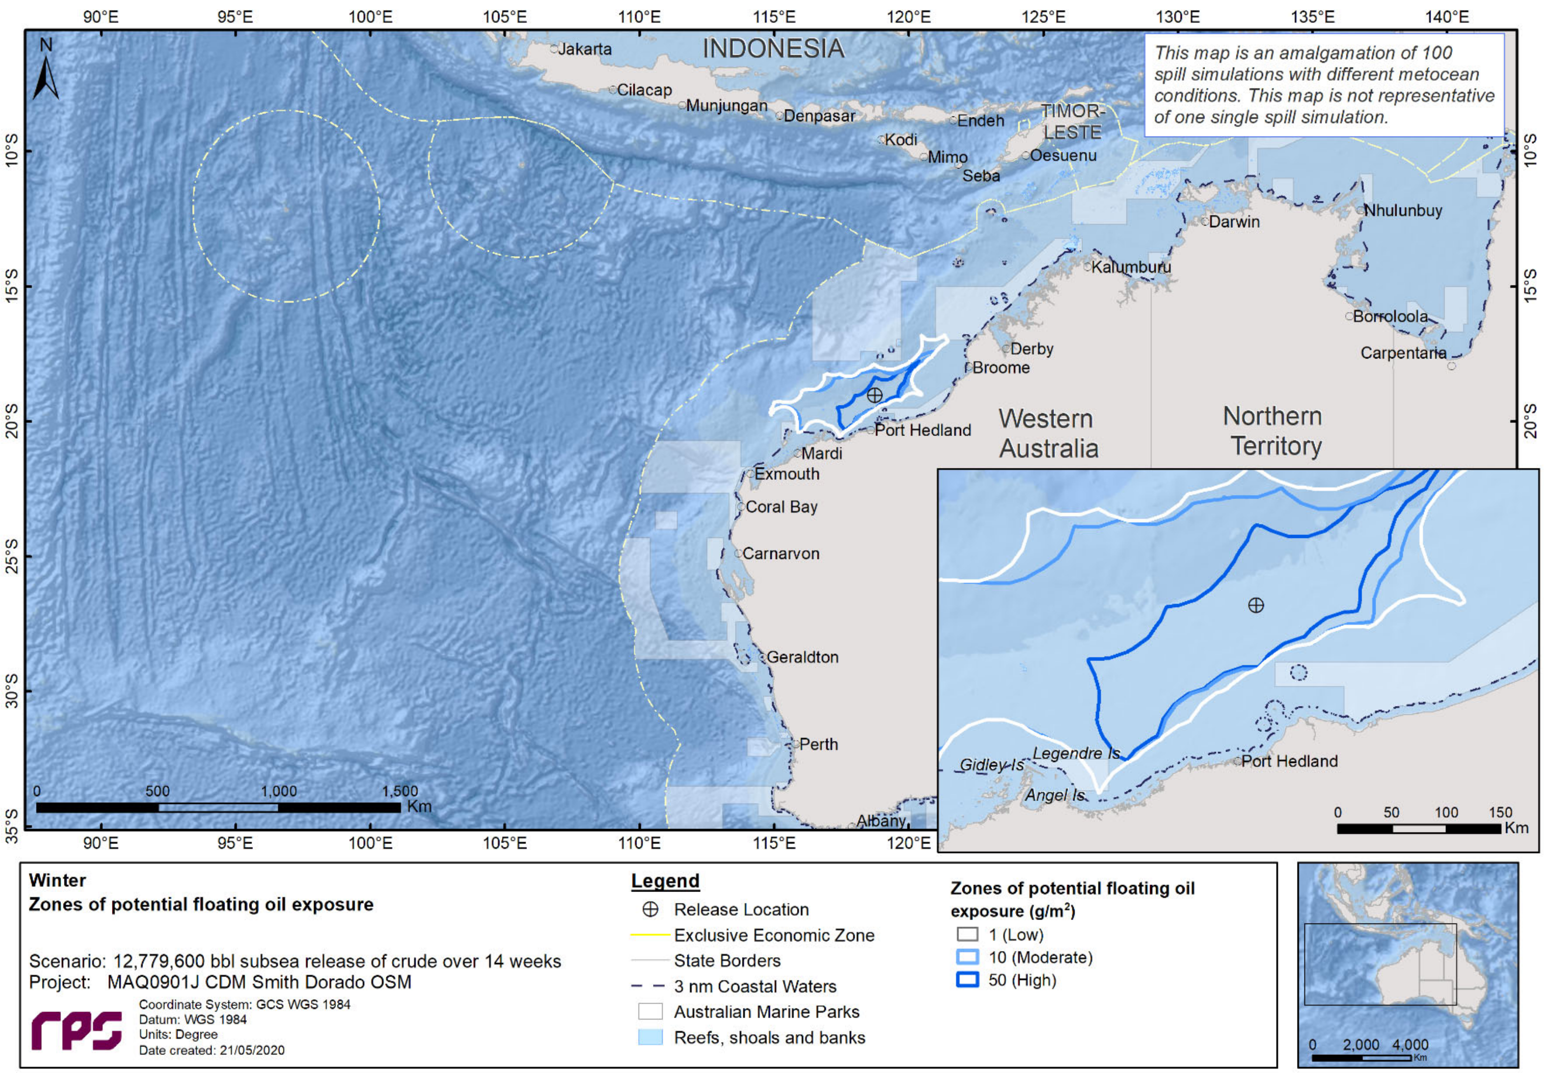

Figure 9.17 Predicted floating oil exposure zones exposure resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.1.3.2 Shoreline Accumulation

Table 9.5 presents a summary of the predicted oil accumulation on any shoreline for all three seasons assessed. The probability of oil accumulation at, or above, the low threshold (10-100 g/m^2) during the summer and transitional seasons was 10% and 1%, respectively. The minimum time before oil accumulation above the low threshold was approximately 11.63 days and 2.88 days, respectively. The greatest volume of oil ashore was 35.8 m^3 and 64.7 m^3 during summer and transitional conditions, respectively. There was no oil accumulation on any shoreline above the low impact threshold predicted for spills commencing during winter conditions.

Table 9.6 and Table 9.7 summarise the oil accumulation to individual sensitive shoreline receptors (as described in Section 7.3) assessed for summer and transitional conditions. Based on combining 100 simulations per season, oil was predicted to accumulate on 4 sensitive shoreline receptors at, or above, the low threshold (10-100 g/m^2) during summer and only 1 receptor (Port Hedland) during transitional conditions. Port Hedland recorded the highest probability of oil accumulation at the low threshold (10-100 g/m^2) during summer conditions (7%) and the quickest time before shoreline accumulation was predicted during transitional conditions at 2.88 days. The greatest volume of oil ashore was 64.7 m^3 and the maximum length of shoreline predicted to have accumulation at the low threshold was 3 km, both occurring at Port Hedland during transitional and summer conditions, respectively.

The maximum potential shoreline loading at low, moderate and high accumulation thresholds are depicted in Figure 9.18 and Figure 9.19 based on the 100 spill simulations commencing during summer and transitional conditions, respectively.

Table 9.5 Summary of oil accumulation on any shoreline. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during all seasonal conditions. The results were calculated from 100 spill simulations per season.

Shoreline Statistics	Summer	Transitional	Winter
Probability of shoreline accumulation at, or above **10 g/m^2** (%)	10	1	-
Minimum time before shoreline accumulation at, or above **10 g/m^2** (days)	11.6	2.9	-
Maximum volume of oil ashore (m^3) from a single simulation	35.8	64.7	-
Average volume of oil ashore (m^3) for all simulations predicted to reach the shorelines	16.0	64.7	-
Maximum length of shoreline accumulation at or above **10 g/m^2** (km) from a single simulation	6.0	2.0	-
Average length of shoreline accumulation at or above **10 g/m^2** (km) for all simulations predicted to reach the shorelines	2.5	2.0	-
Maximum length of shoreline accumulation at or above **100 g/m^2** (km) from a single simulation	2.0	2.0	-
Average length of shoreline accumulation at or above **100 g/m^2** (km) for all simulations predicted to reach the shorelines	2.0	2.0	-
Maximum length of shoreline accumulation at or above **1,000 g/m^2** (km) from a single simulation	1.0	2.0	-
Average length of shoreline accumulation at or above **1,000 g/m^2** (km) for all simulations predicted to reach the shorelines	1.0	2.0	-

Table 9.6 Summary of oil accumulation on individual shorelines. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Shoreline receptor	Maximum probability of shoreline accumulation (%)			Minimum time before shoreline accumulation (days)			Load on shoreline (g/m^2)		Volume on shoreline (m^3)		Mean length of shoreline accumulation (km)			Maximum length of shoreline accumulation (km)		
	Low	Mod.	High	Low	Mod.	High	Mean	Peak	Mean	Peak	Low	Mod.	High	Low	Mod.	High

Table 9.7 Summary of oil accumulation on individual shorelines. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during transitional (April and September) conditions. The results were calculated from 100 spill simulations.

Shoreline receptor	Maximum probability of shoreline accumulation (%)			Minimum time before shoreline accumulation (days)			Load on shoreline (g/m^2)		Volume on shoreline (m^3)		Mean length of shoreline accumulation (km)			Maximum length of shoreline accumulation (km)		
	Low	Mod.	High	Low	Mod.	High	Mean	Peak	Mean	Peak	Low	Mod.	High	Low	Mod.	High
Barrow Island	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-
Cunningham Island	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-
Imperieuse Reef	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-	-
Port Hedland	1	1	1	2.9	2.9	2.9	3,061.5	3,061.5	64.7	64.7	2.0	2.0	2.0	2.0	2.0	2.0

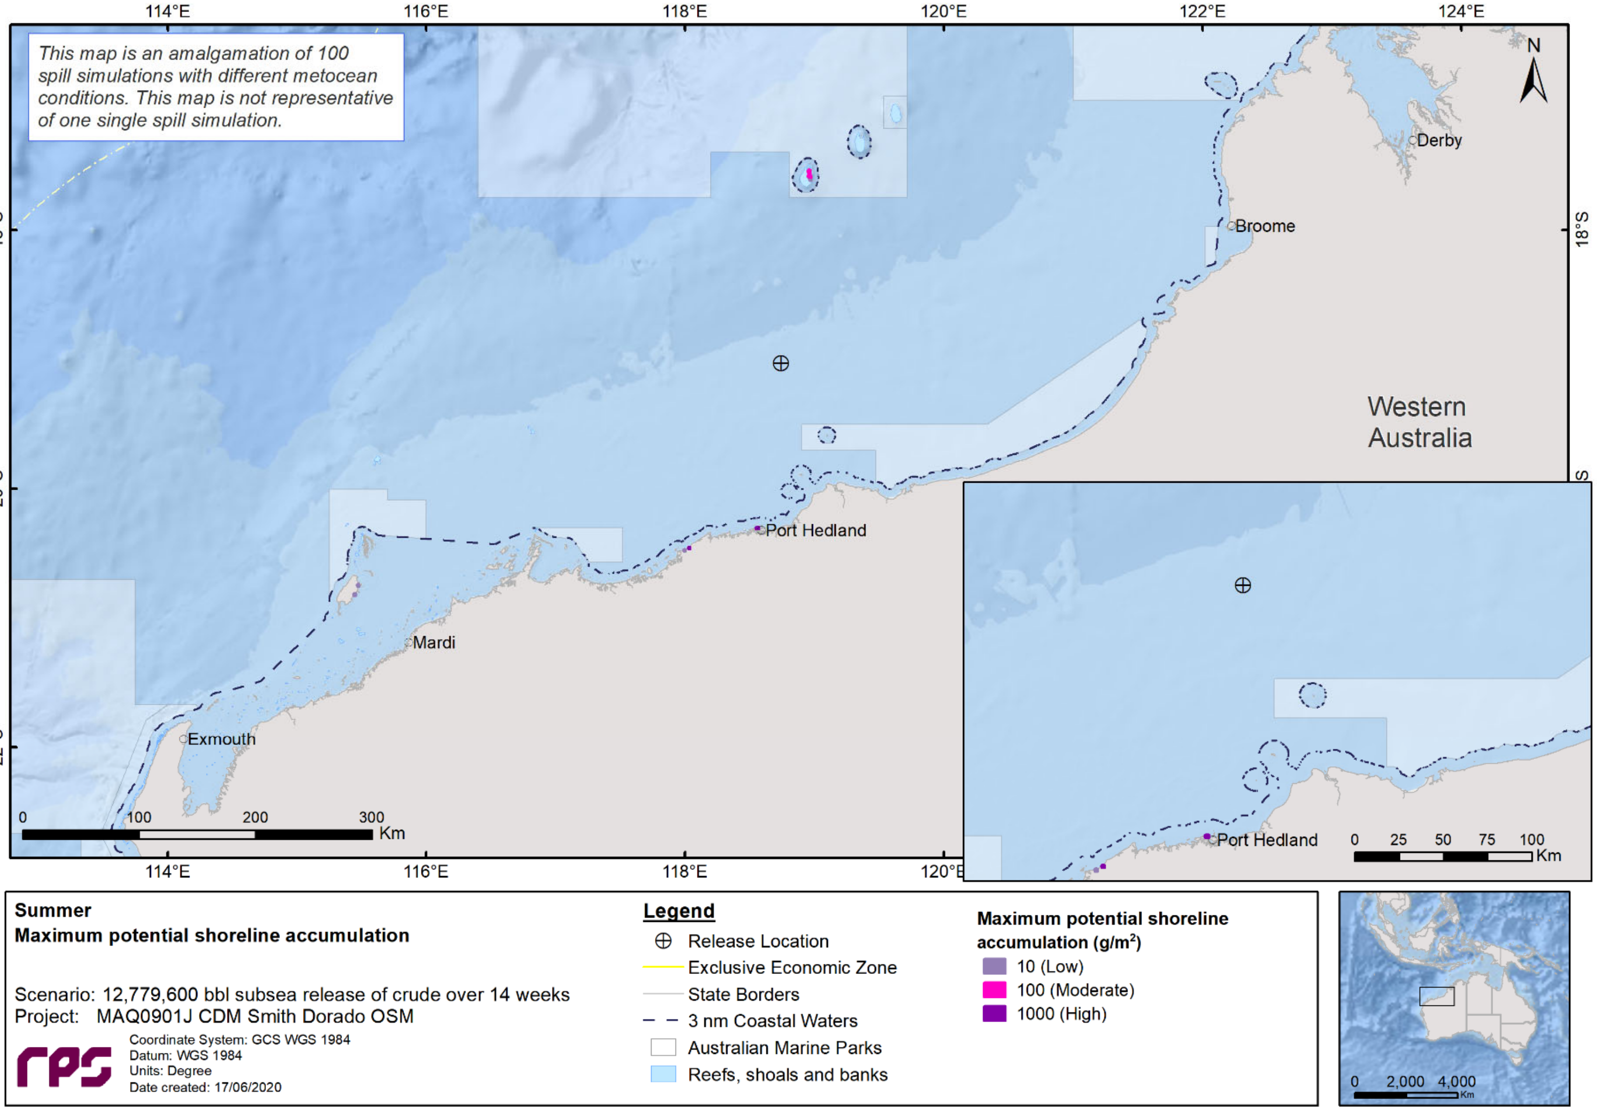

Figure 9.18 Predicted maximum shoreline loading resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

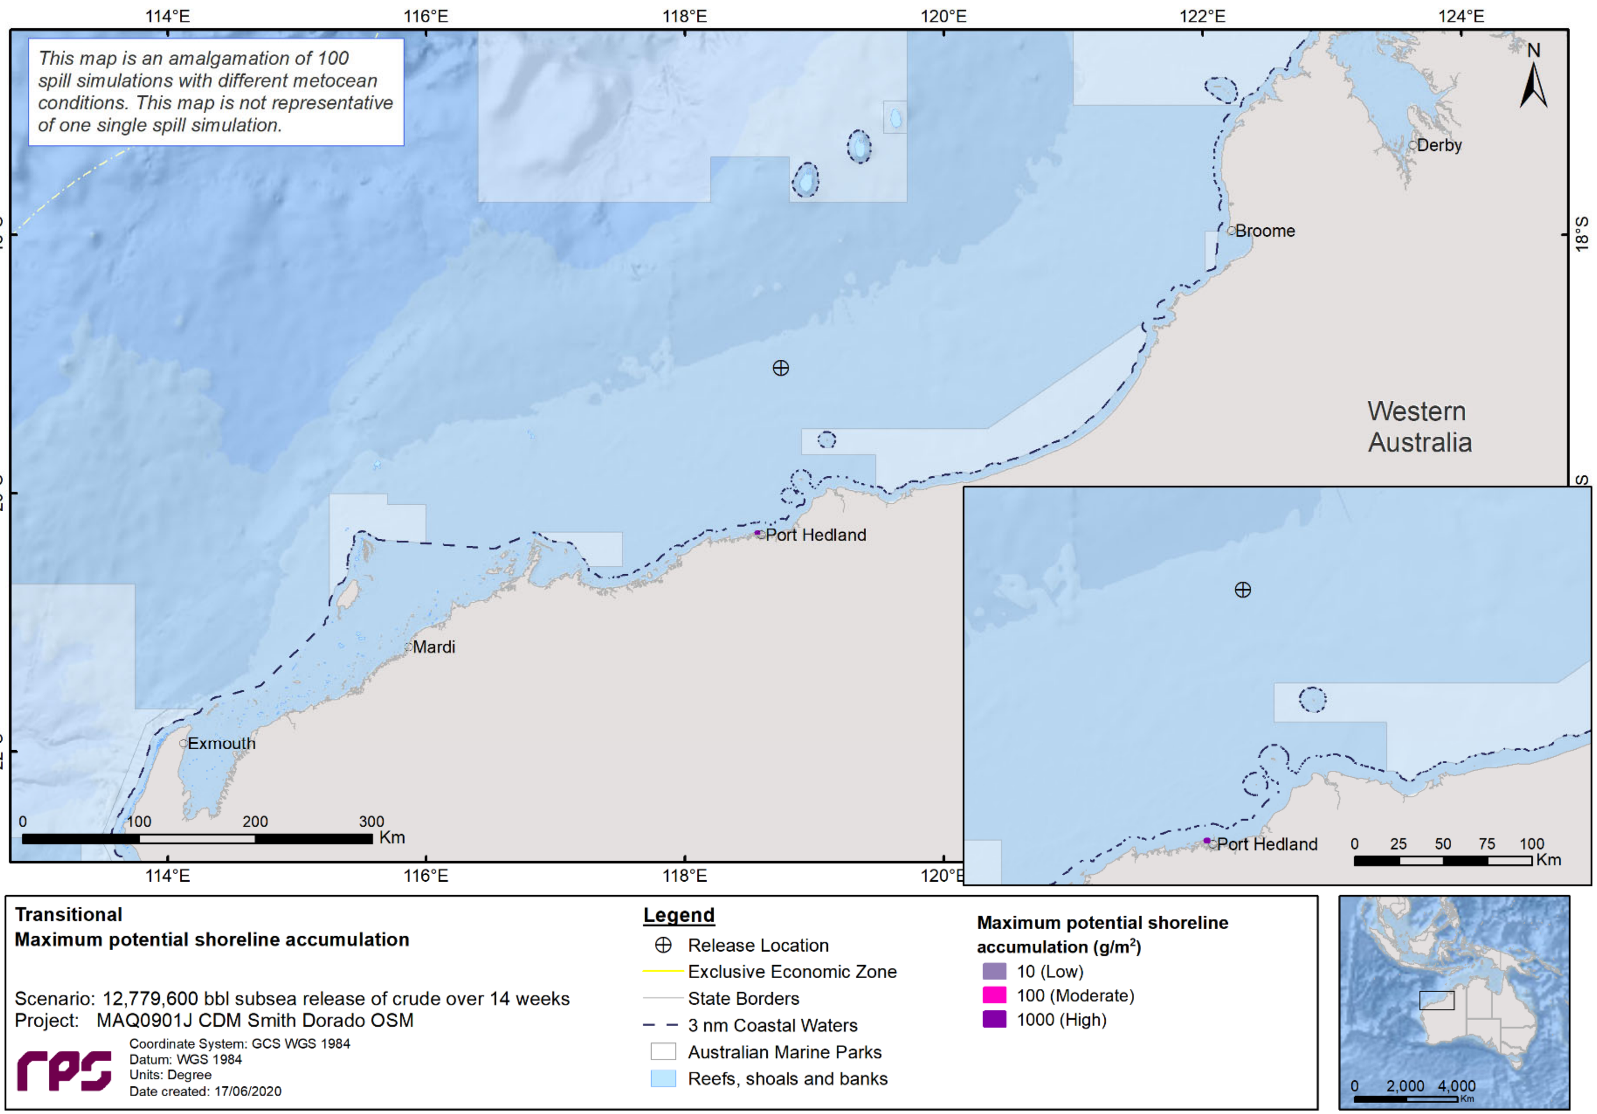

Figure 9.19 Predicted maximum shoreline loading resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

9.1.3.3 Entrained Hydrocarbons

Images of entrained hydrocarbon exposure zones in the 0-10 m depth layer are depicted in Figure 9.20 Figure 9.21 and Figure 9.22 for the combined 100 spill simulations each commencing during summer, transitional and winter conditions, respectively. The results indicated that exposure at the low threshold was predicted to occur up to a maximum distance of 2,878 km (west-northwest) from the spill site during winter conditions. This distance reduced to 2,158 km (west-northwest) based on the moderate threshold in winter conditions. The maximum distances for summer and transitional conditions at the low threshold were 2,635 km and 2,498 m, respectively. The maximum distances at the moderate threshold were reduced for summer (1,964 km) and transitional (1,739 km).

Table 9.8 to Table 9.10 summarise the probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer for each season. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at the shallowest depth from the sea surface for each KEF (representing the maximum concentrations).

There are a total of 20 AMPs within the low exposure zone across the three seasons (cumulative envelope of all the oil spill simulations), with Montebello AMP recording the highest probability of exposure during summer (95%), while Argo Rowley AMP had the highest probabilities for transitional (97%) and winter (100%) seasons. The shortest time for entrained hydrocarbons at the low threshold (10-100 ppb) to reach an AMP was recorded at Dampier during transitional conditions (2.67 days). Eighteen AMPs were within the moderate exposure zone (cumulative of 100 simulations) during summer reducing to 12 AMPs for cumulative spills moderate exposure zone commencing in winter conditions.

RSB receptors within the low exposure zone was predicted to vary between seasons (103 summer, 83 transitional and 74 winter). The highest probability of exposure was predicted at Rankin Bank during winter conditions (99%). The quickest time for entrained hydrocarbons at the low threshold to reach an RSB receptor was predicted at Madeleine Shoals (4 days during transitional conditions).

Entrained hydrocarbons at the low threshold were predicted to cross into WA State Waters during every season with probabilities ranging from 81-94%. The minimum time before oil crossed the WA State Waters boundary was 2.71 days, for a spill commencing during transitional conditions.

Table 9.8 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer unless specified otherwise. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of entrained hydrocarbon exposure		Minimum time (days) before entrained hydrocarbon exposure at any depth		Maximum entrained hydrocarbon concentration (ppb)

Table 9.9 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during transitional (April and September) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of entrained hydrocarbon exposure		Minimum time (days) before entrained hydrocarbon exposure at any depth		Maximum entrained hydrocarbon concentration (ppb)
		Low (10-100 ppb)	Moderate (≥ 100 ppb)	Low (10-100 ppb)	Moderate (≥ 100 ppb)	for a single simulation at any depth

Table 9.10 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during winter (May to August) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of entrained hydrocarbon exposure		Minimum time (days) before entrained hydrocarbon exposure at any depth		Maximum entrained hydrocarbon concentration (ppb)
		Low (10-100 ppb)	Moderate (≥ 100 ppb)	Low (10-100 ppb)	Moderate (≥ 100 ppb)	for a single simulation at any depth

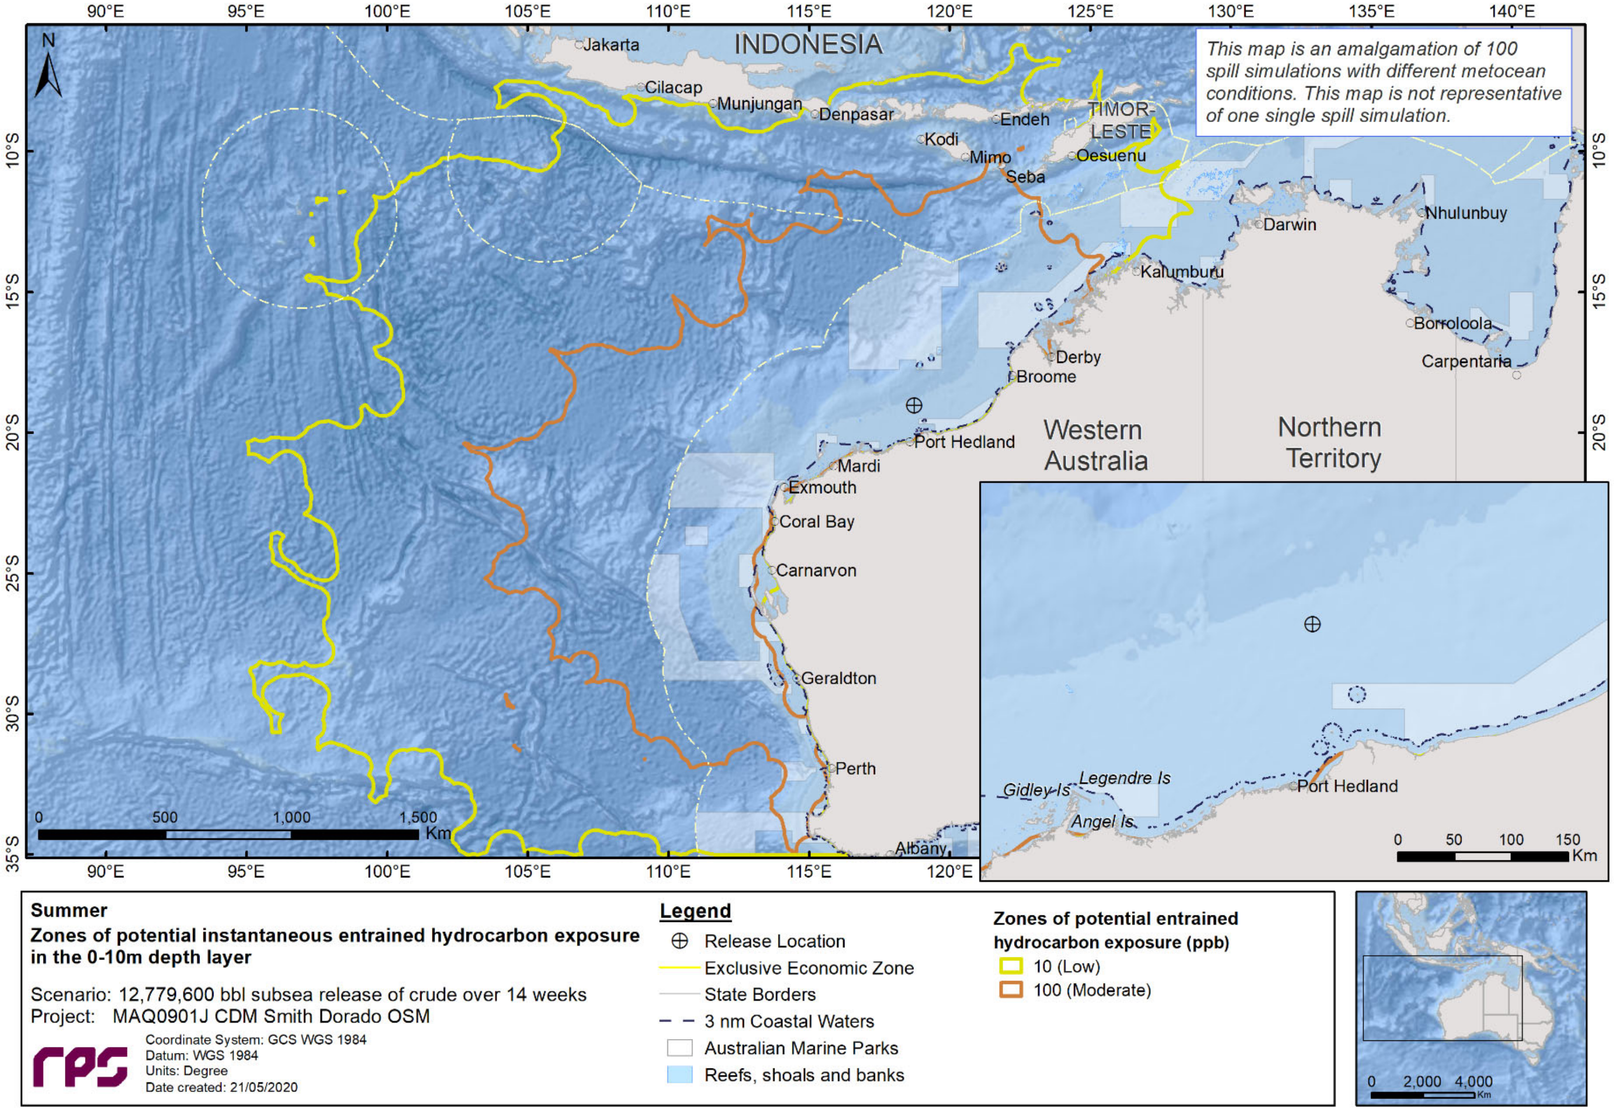

Figure 9.20 Predicted entrained hydrocarbon exposure zones resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

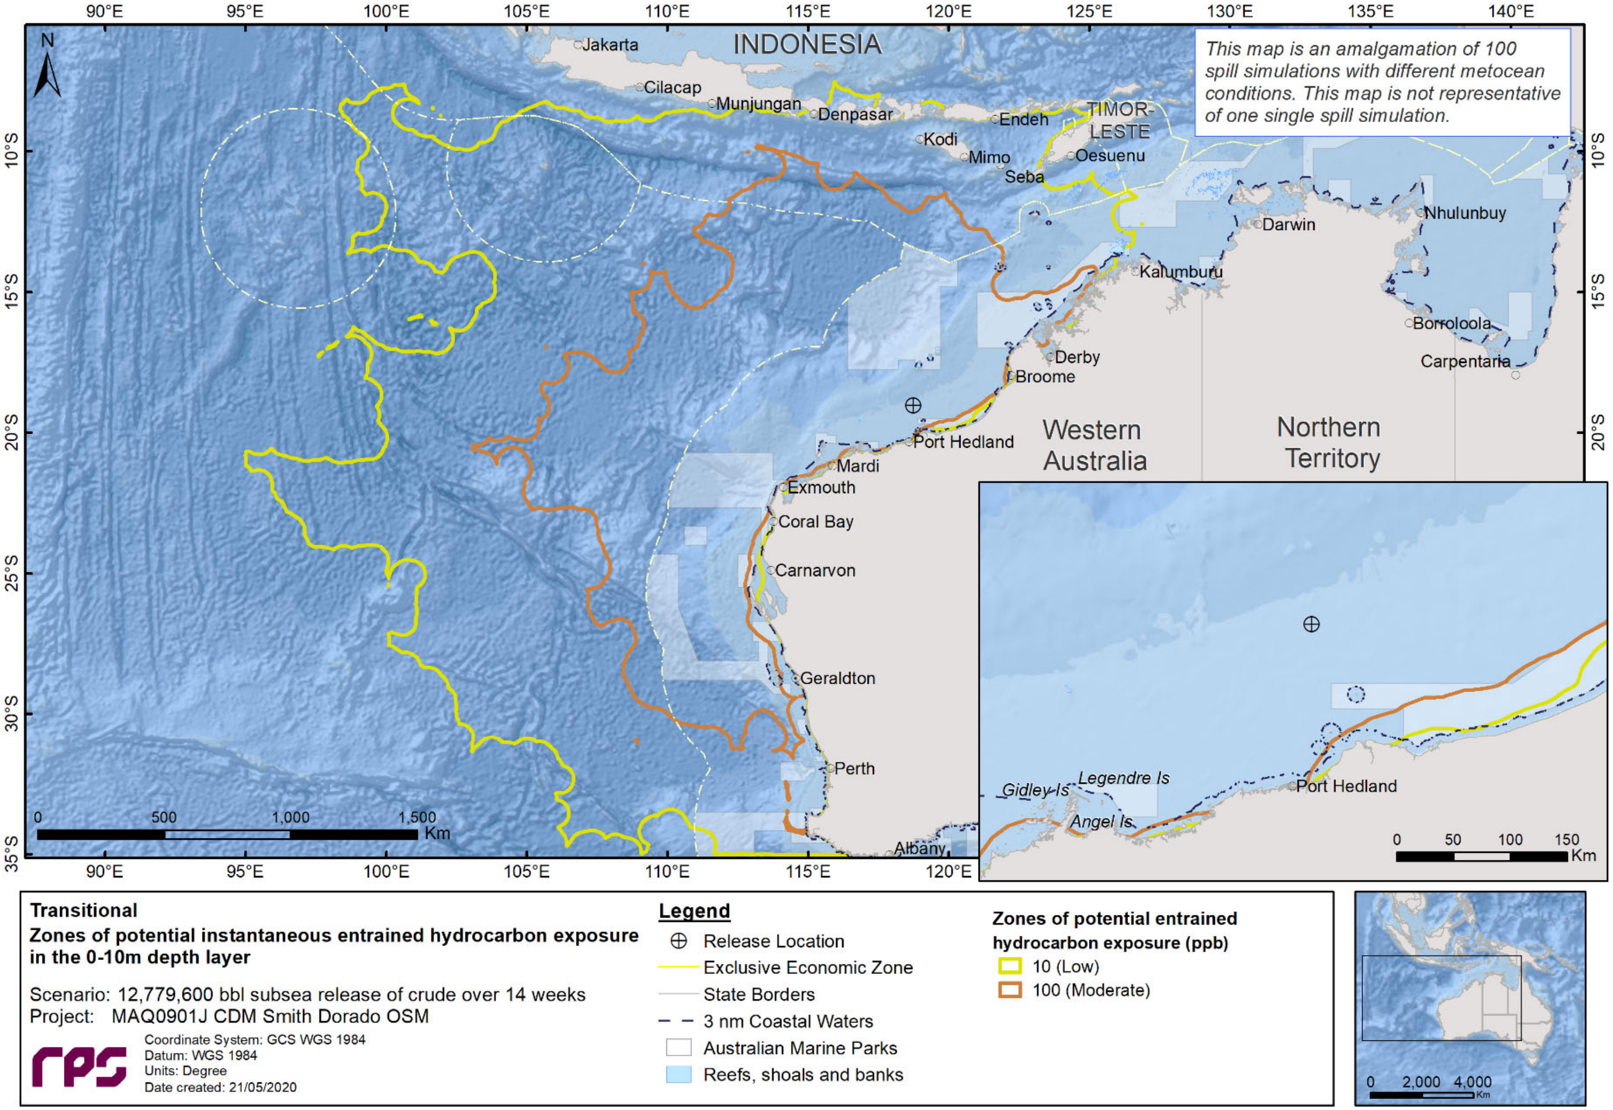

Figure 9.21 Predicted entrained hydrocarbon exposure zones resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

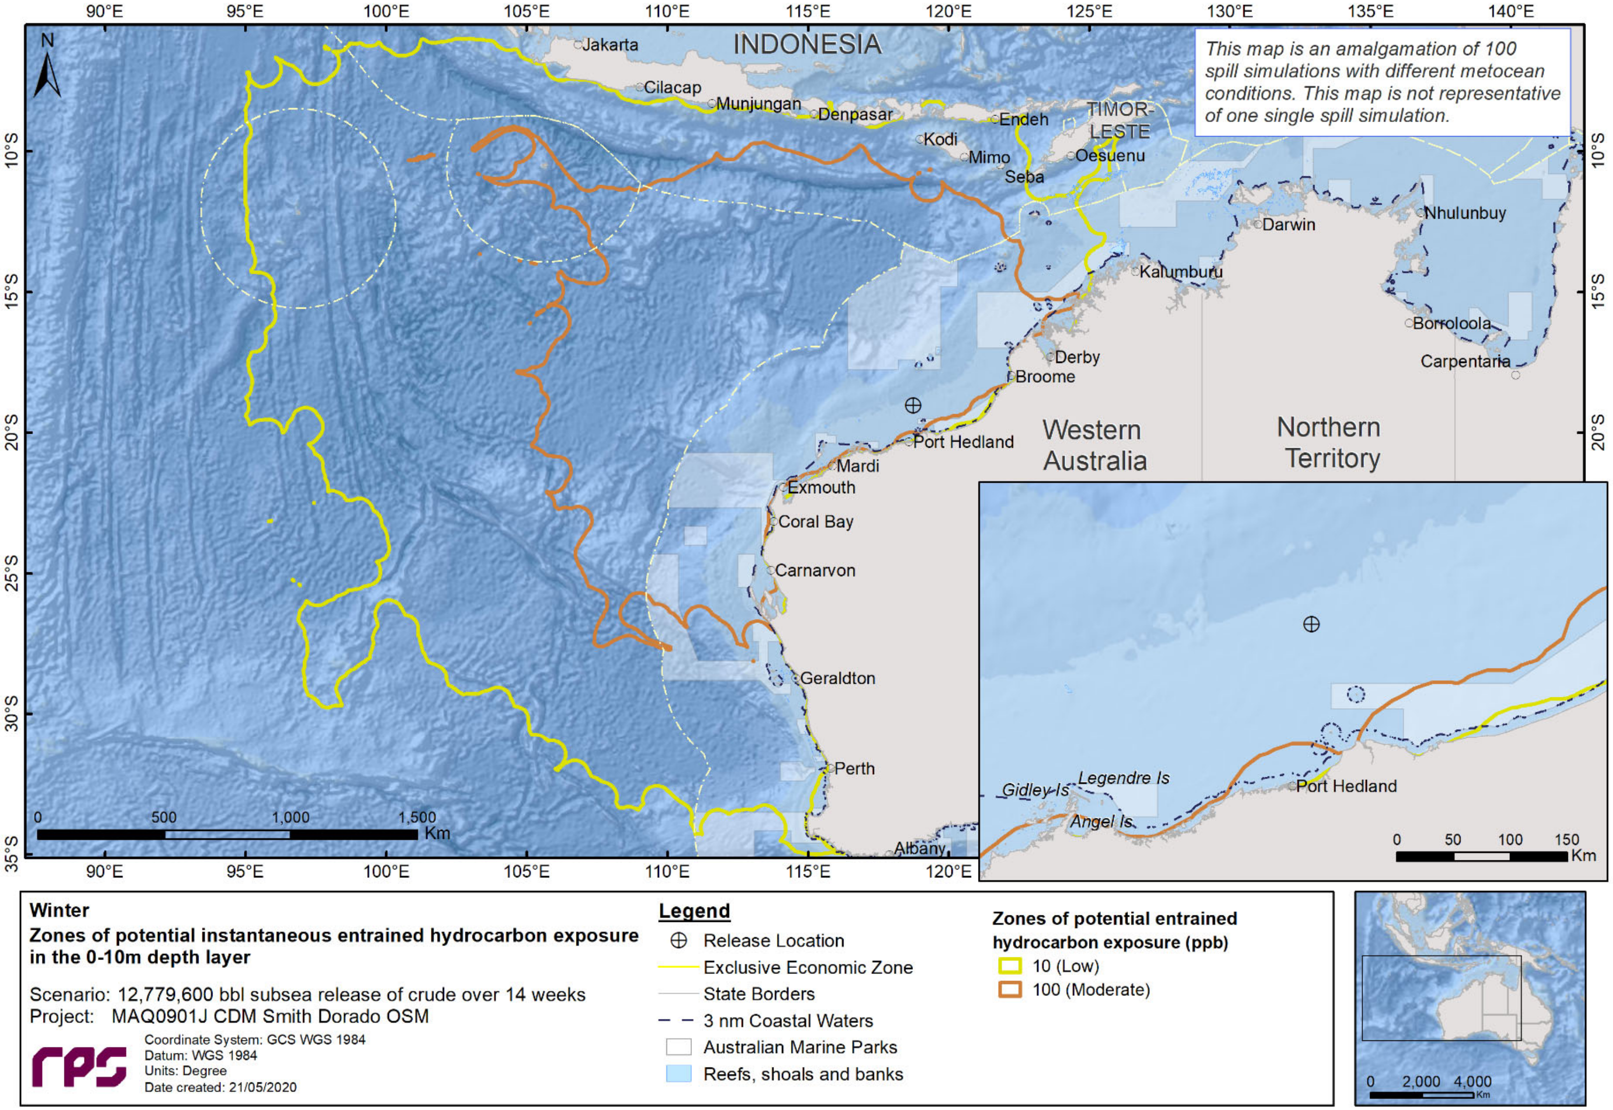

Figure 9.22 Predicted entrained hydrocarbon exposure zones resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.1.3.4 Dissolved Hydrocarbons

Images of dissolved hydrocarbon exposure zones (0-10 m depth layer) are depicted in Figure 9.23, Figure 9.24 and Figure 9.25 for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively. The maximum distance from the spill site to the low exposure threshold (10-50 ppb) for summer, transitional and winter results were 1,581 km (west-southwest), 1,321 km (south southwest) and 1,339 km (west), respectively. This distance reduced to 1,342 km (southwest; summer), 1,124 km (southwest; transitional) and 1,171 km (southwest; winter) as the threshold increased to moderate (50 – 400 ppb). Based on the high threshold (≥400 ppb) the distance reduced further to 930 km (west southwest; summer), 582 km (west southwest; transitional) and 843 km (southwest; winter).

Table 9.11 to Table 9.13 summarise the probability of exposure to receptors from instantaneous dissolved hydrocarbon thresholds in the 0-10 m depth layer. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at their shallowest depth from the sea surface.

Eleven AMPs during transitional conditions and 12 AMPs during summer and winter are within the low exposure zone. The Argo-Rowley Terrace AMP recorded the greatest probability of exposure of 74% during winter conditions. The shortest time for dissolved hydrocarbon exposure at the low threshold to an AMP was recorded at Dampier during transitional conditions (2.67 days).

A total of 45 RSB receptors are within the dissolved hydrocarbon low exposure zone across the 3 seasons. The highest probability of exposure predicted at Rankin Bank during winter conditions (72%). The quickest time before low exposure at a RSB receptor was 7 days at Rankin Bank during transitional conditions.

Dissolved hydrocarbons at the low threshold were predicted to cross into WA State Waters during every season with probabilities ranging from 38-64%. The minimum time before dissolved hydrocarbons at the low threshold crossed the WA State Waters boundary was 2.83 days, for a spill commencing during transitional conditions.

Table 9.11 Probability of exposure to individual receptors from instantaneous dissolved hydrocarbons in the 0-10 m depth layer. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Table 9.12 Probability of exposure to individual receptors from instantaneous dissolved hydrocarbons in the 0-10 m depth layer. Results are based on a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during transitional (April and September) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of dissolved hydrocarbon exposure			Minimum time (days) before dissolved hydrocarbon exposure at any depth			Maximum dissolved hydrocarbon concentration (ppb)
		Low (10-50ppb)	Moderate (50-400 ppb)	High (≥400 ppb)	Low (10-50ppb)	Moderate (50-400 ppb)	High (≥400 ppb)	for a single simulation at any depth

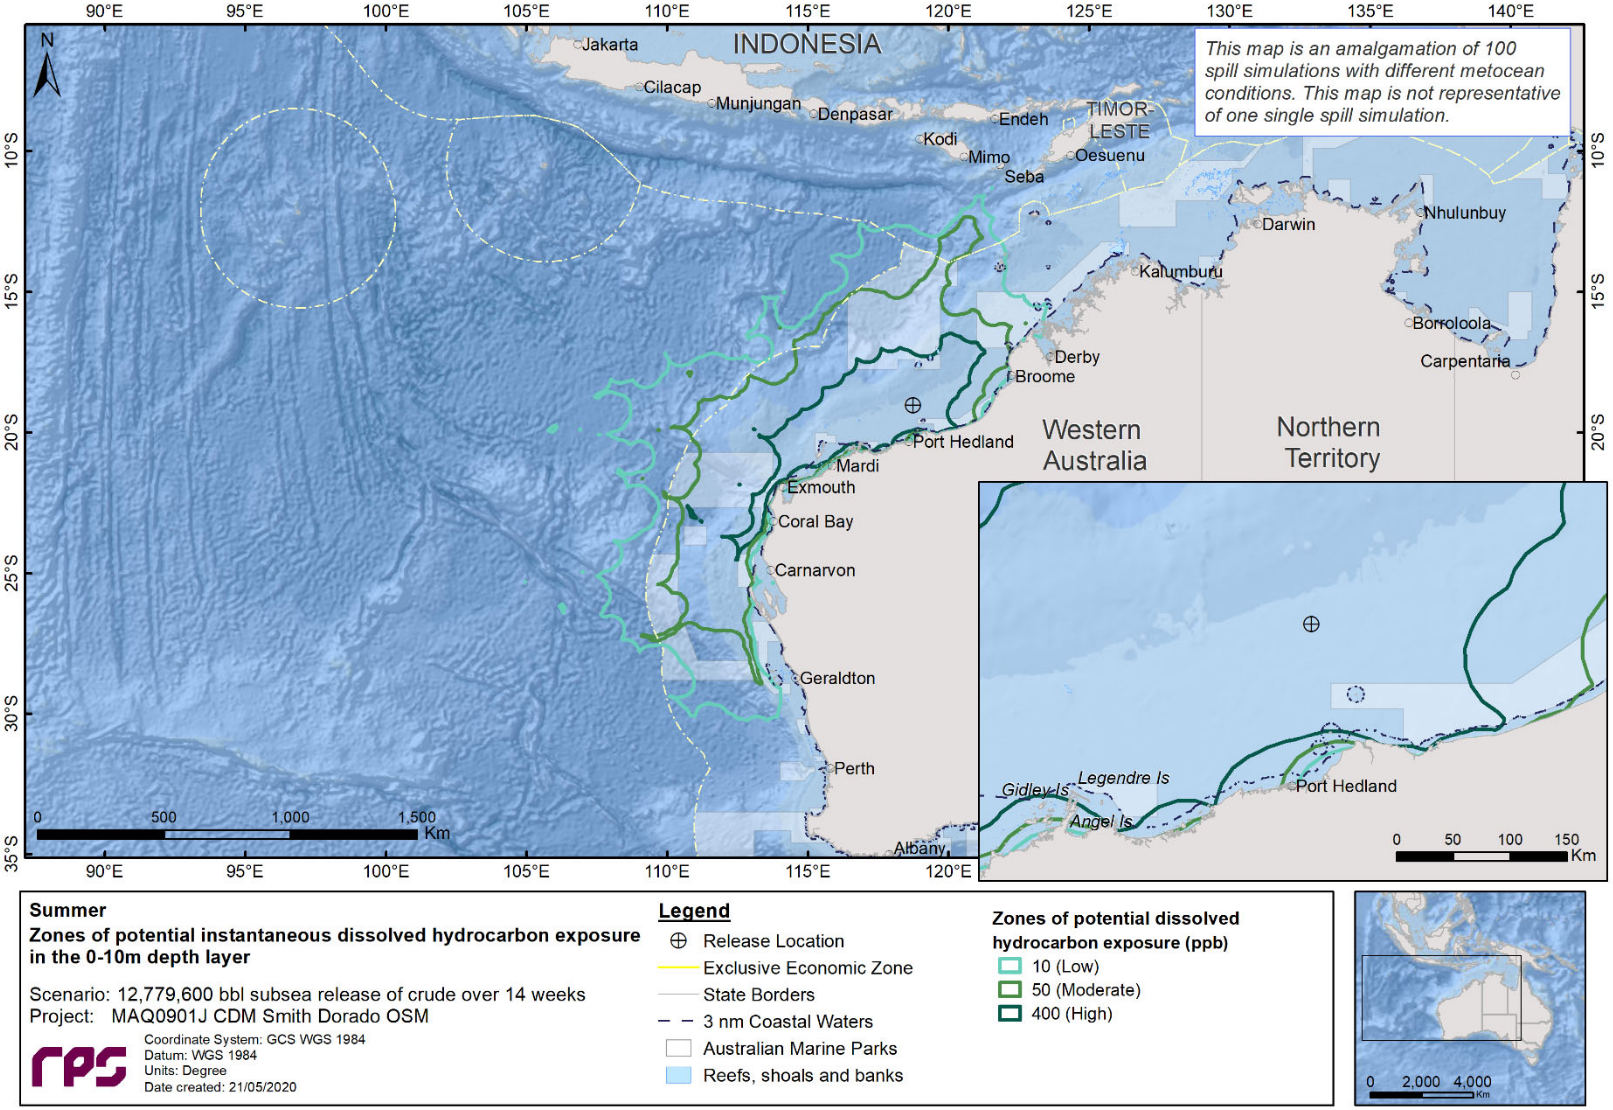

Figure 9.23 Predicted dissolved hydrocarbon exposure zones resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

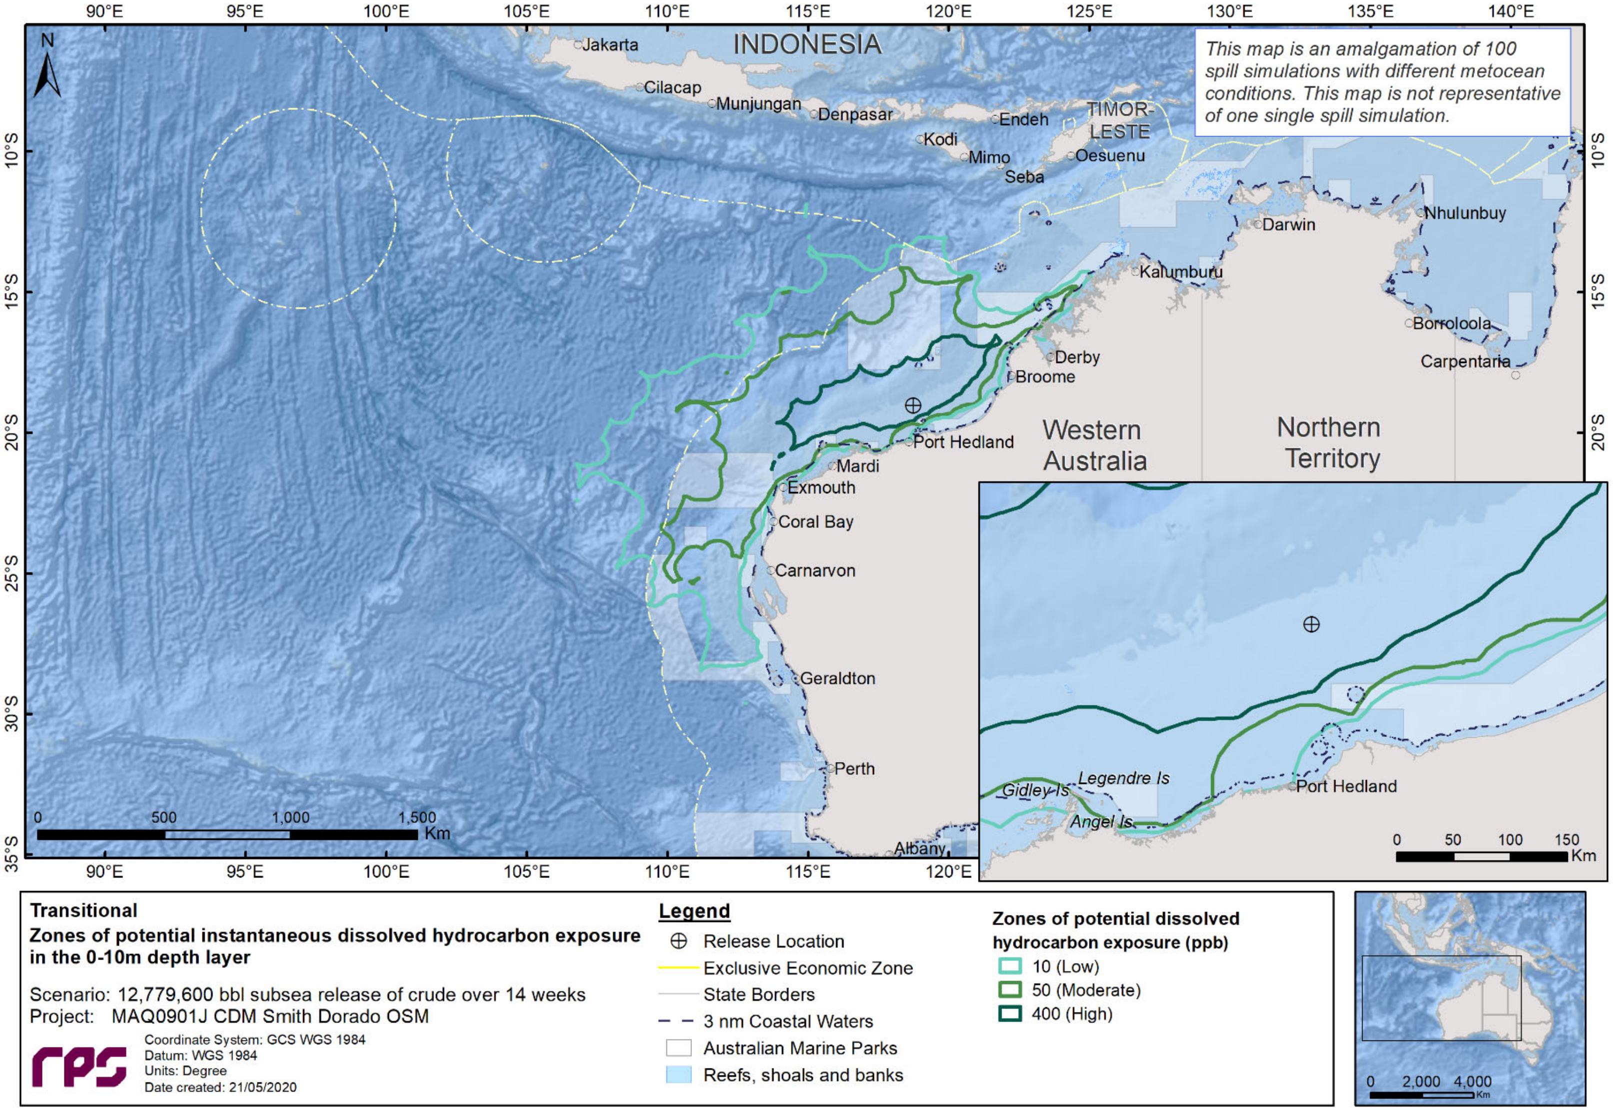

Figure 9.24 Predicted dissolved hydrocarbon exposure zones resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

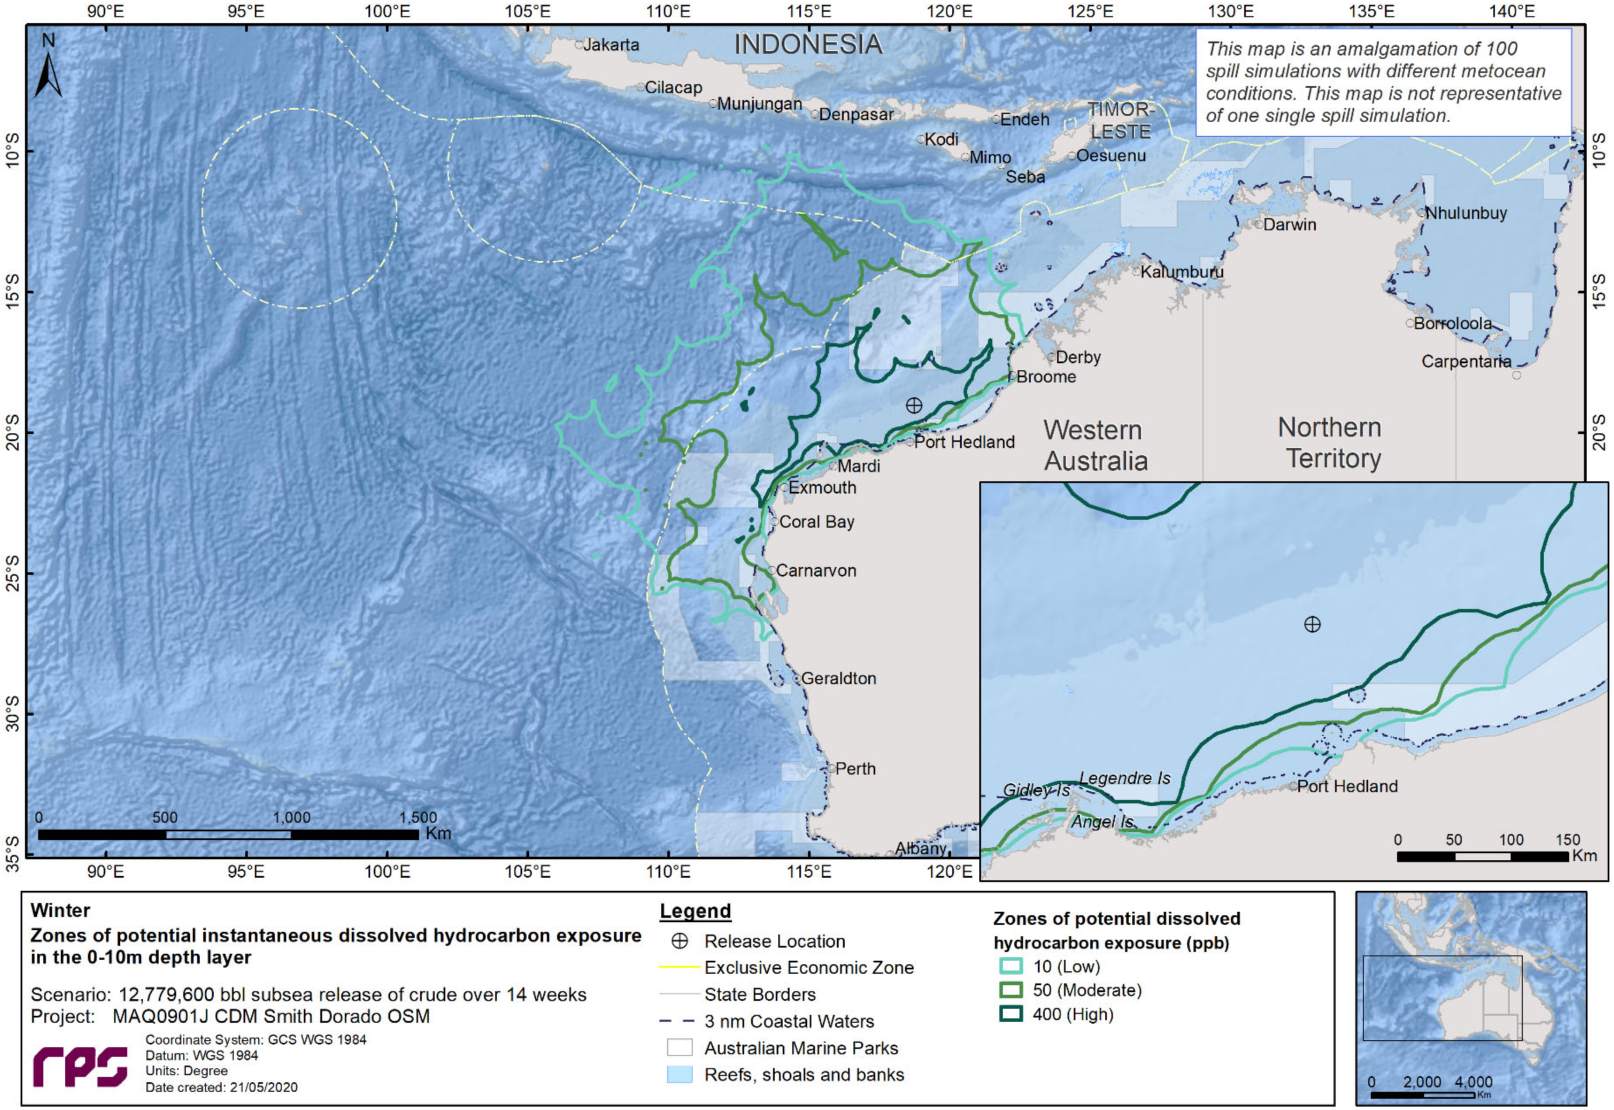

Figure 9.25 Predicted dissolved hydrocarbon exposure zones resulting from a subsea blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.2 Scenario 2: Simulation of a 14-week surface blowout of crude at the WHP

This scenario examined a 12,779,600 bbl (2,031,794 m^3) surface release of crude with a decreasing discharge rate over 14 weeks. A total of 300 simulations were run (i.e. 100 spills per season) and each was tracked for 118 days. These are then combined and presented as exposures zones for each season (cumulative of 100 simulations) for the low, moderate and high thresholds.

Sections 9.2.1 presents the overview of the EMBA based on combining the 300 spill simulations and Section 9.2.3 shows the seasonal (or stochastic) analysis, while Section 9.2.2 presents the deterministic analysis results (i.e. a single spill simulation), based on largest volume ashore and longest length of oiled shoreline.

9.2.1 Overview

Figure 9.26 and Figure 9.27 are maps which encompass the full geographic EMBA derived by overlaying the combined results from all 300 spill simulations at both the low and moderate exposure thresholds, respectively.

Figure 9.28 and Figure 9.29 show the annualised extent of floating oil and in-water (entrained and dissolved) exposure as well as shoreline accumulation based on the low and moderate exposure thresholds, respectively, derived from combining the results from all 300 spill simulations.

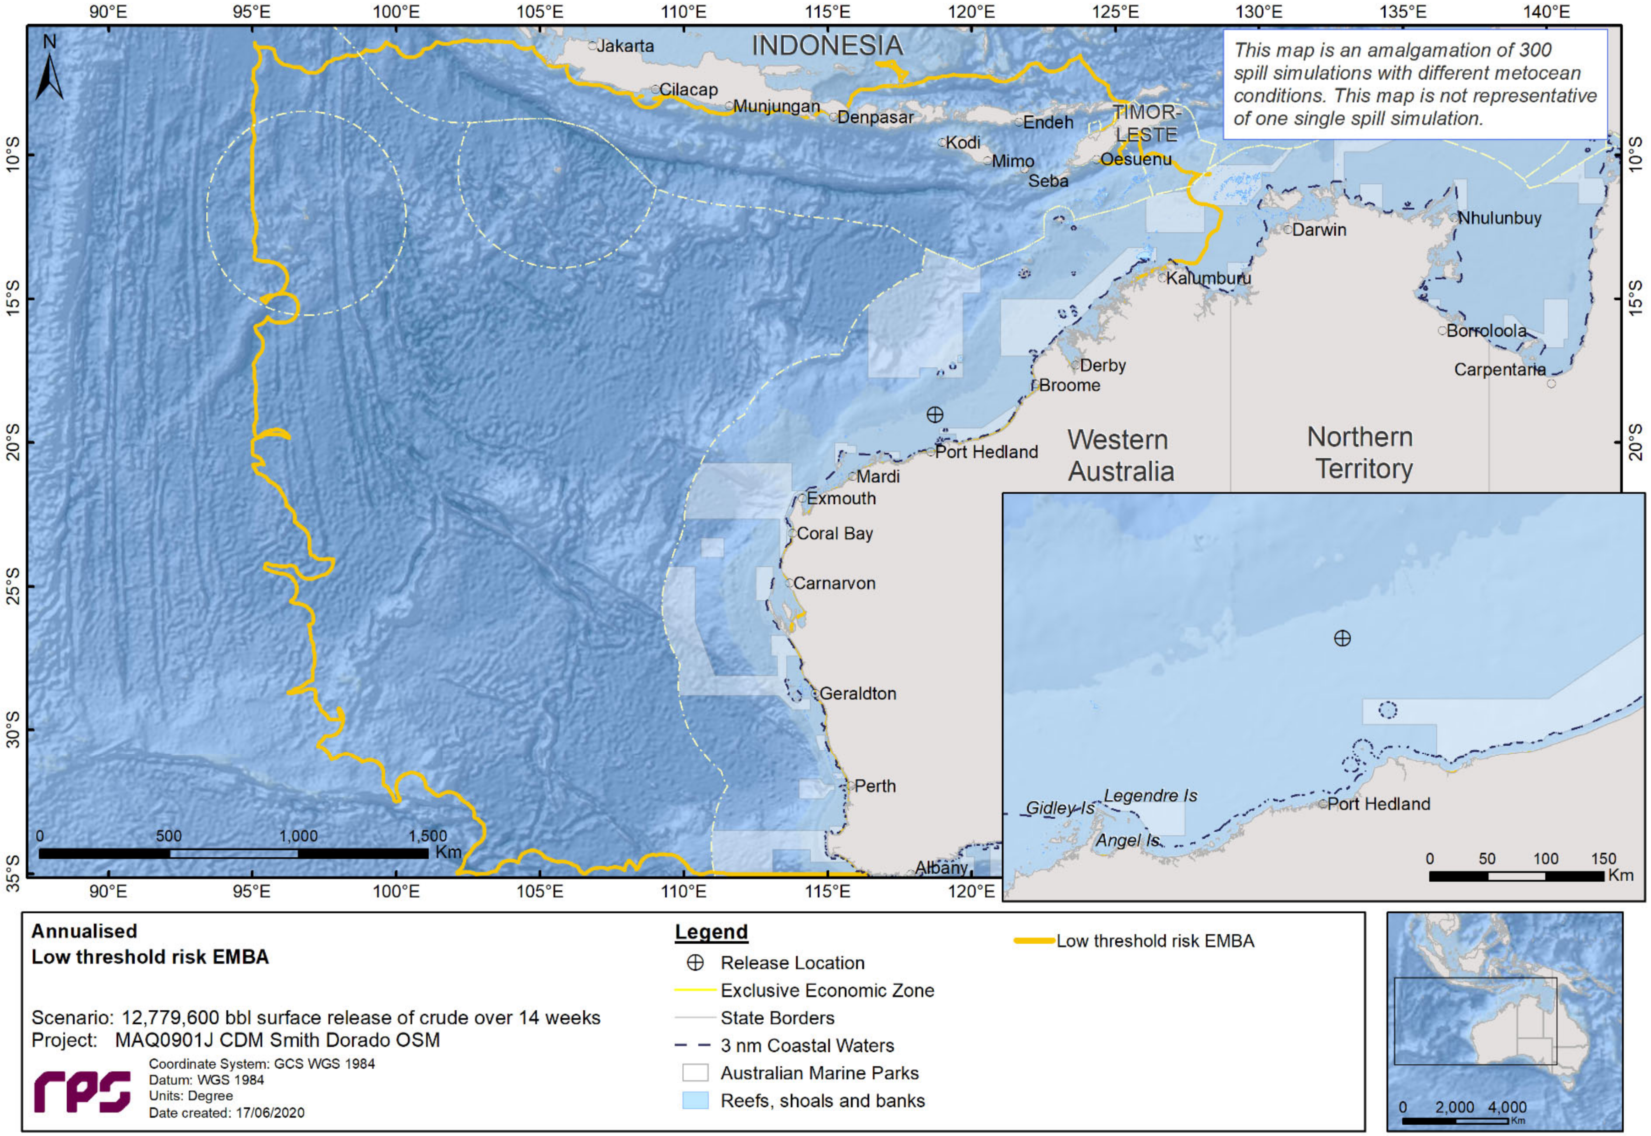

Figure 9.26 Predicted low threshold risk EMBA resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The annualised results were calculated from 300 spill simulations, which were tracked for 118 days.

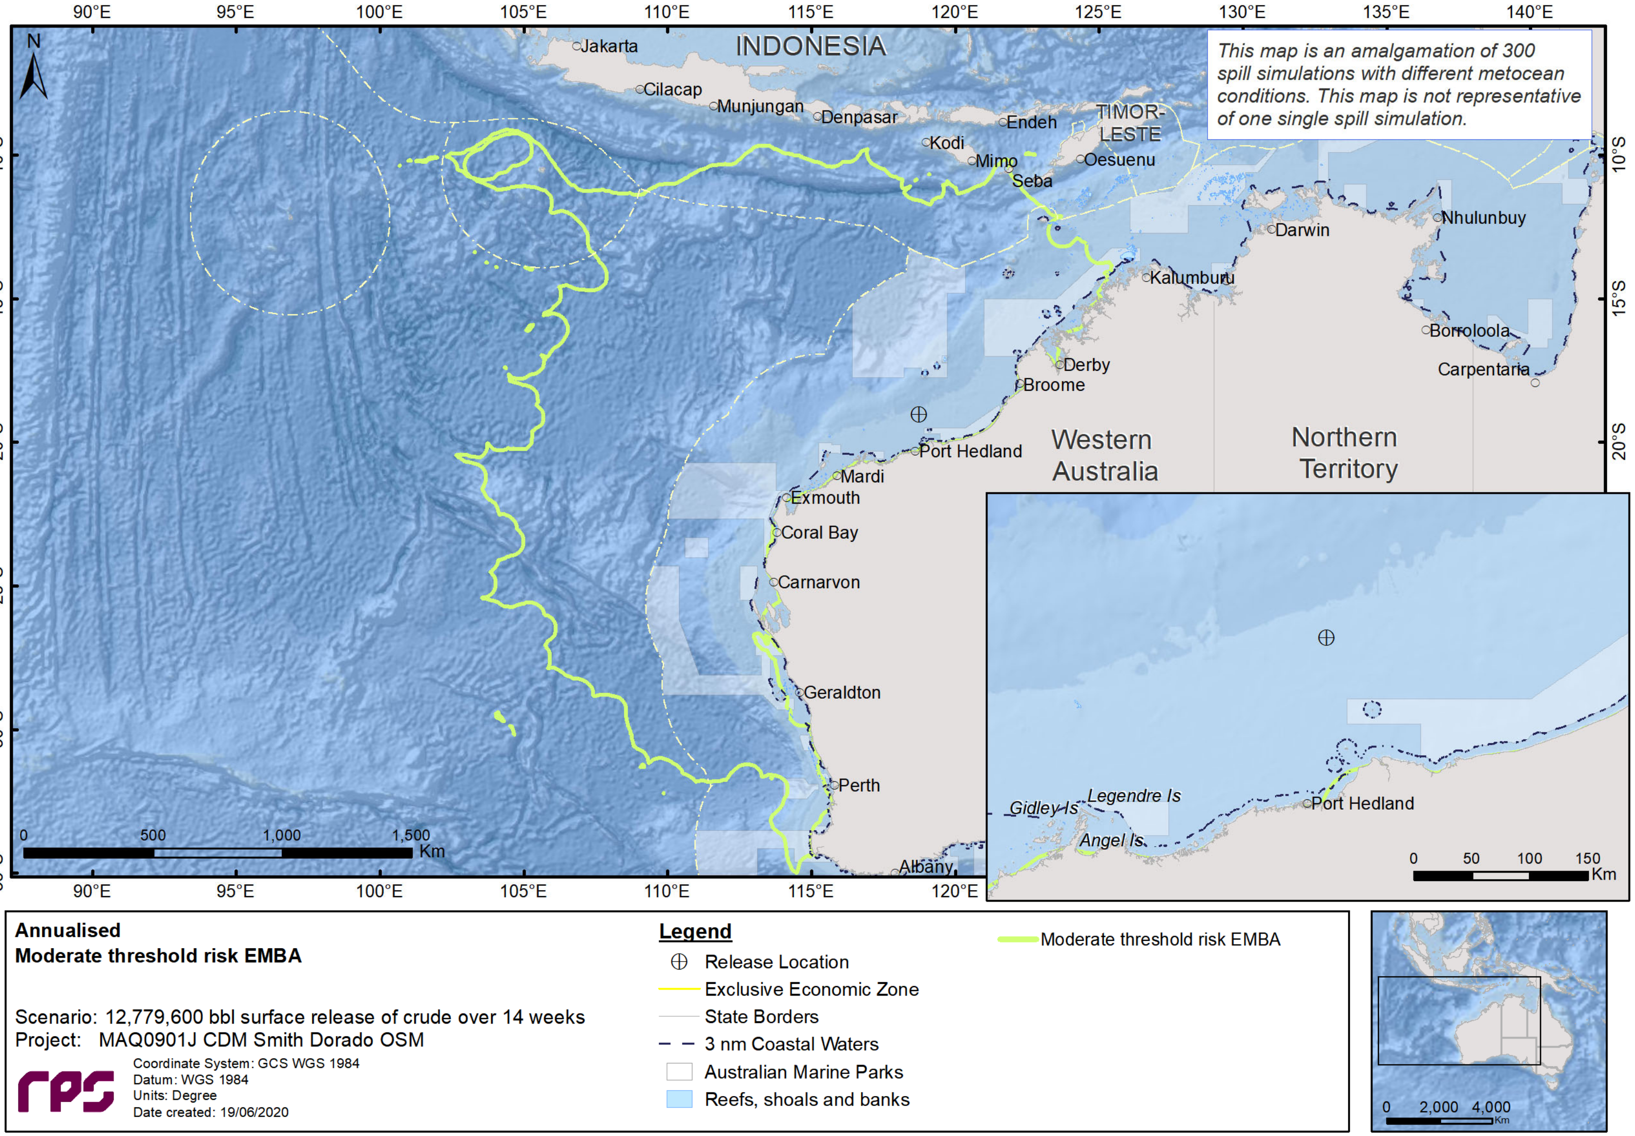

Figure 9.27 Predicted moderate threshold risk EMBA resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The annualised results were calculated from 300 spill simulations, which were tracked for 118 days.

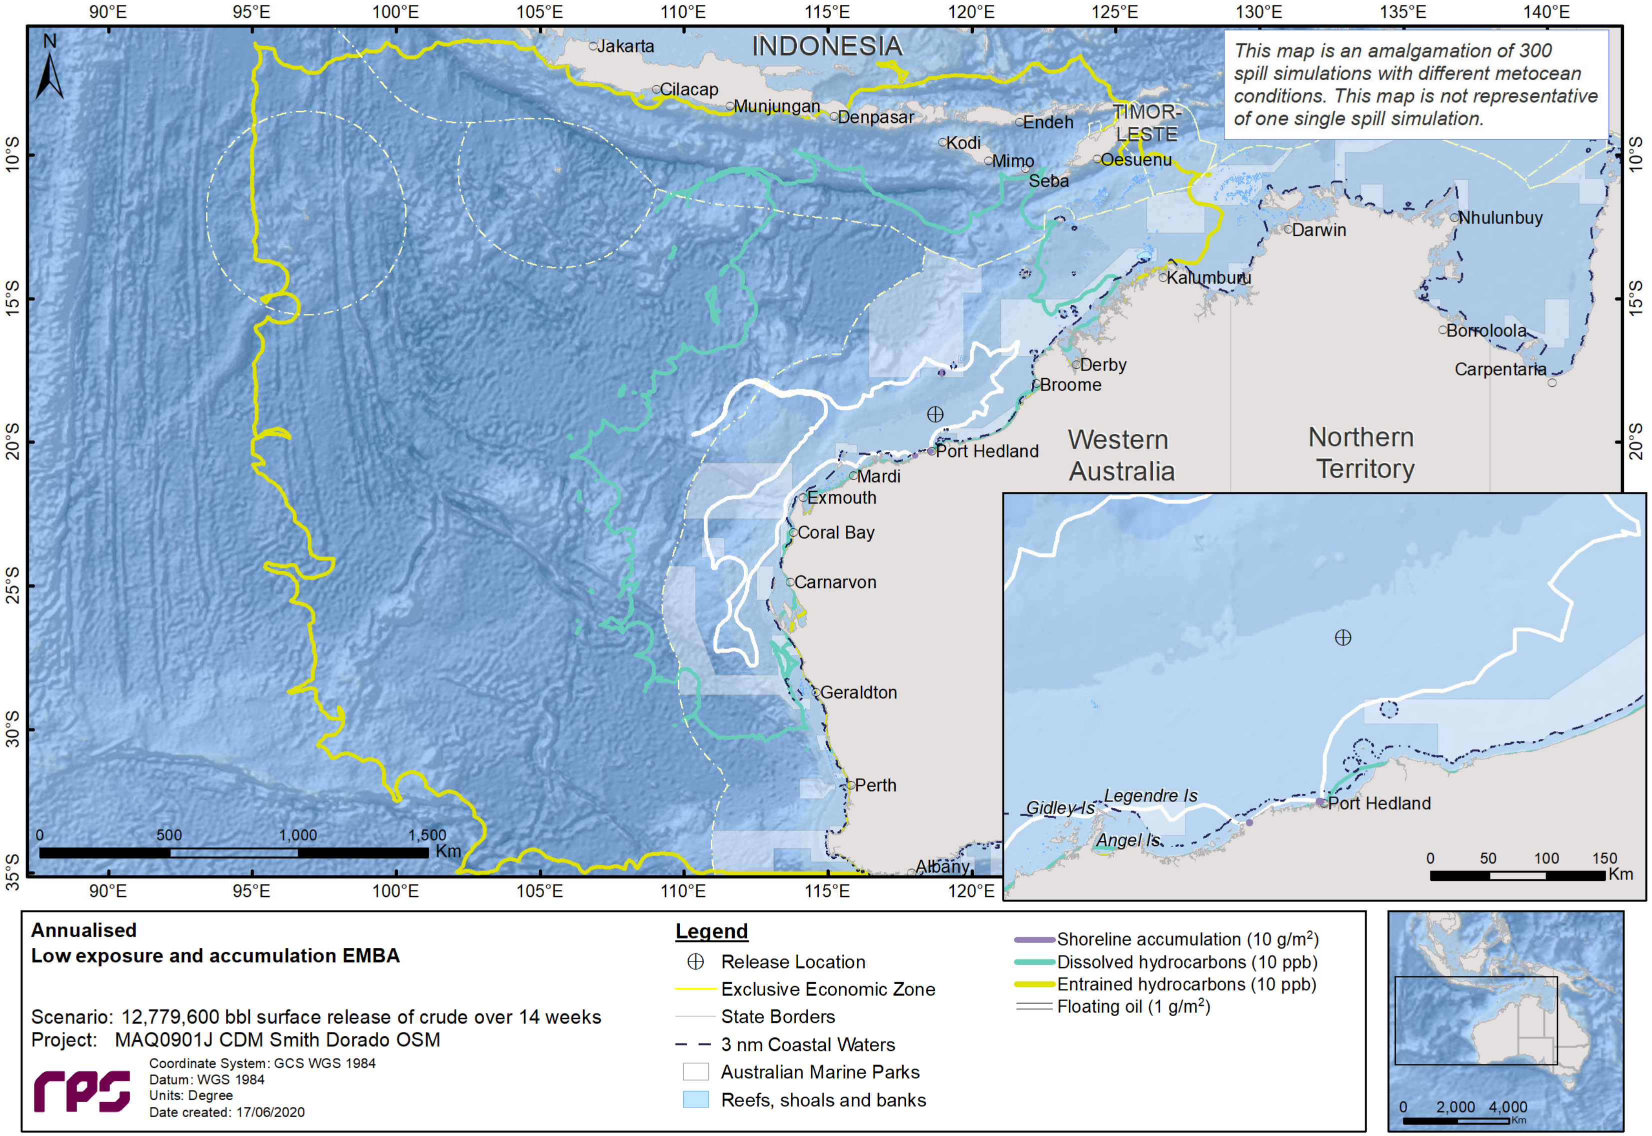

Figure 9.28 Annualised low threshold oil exposure and shoreline accumulation resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP. The annualised results were calculated from 300 spill simulations, which were tracked for 118 days.

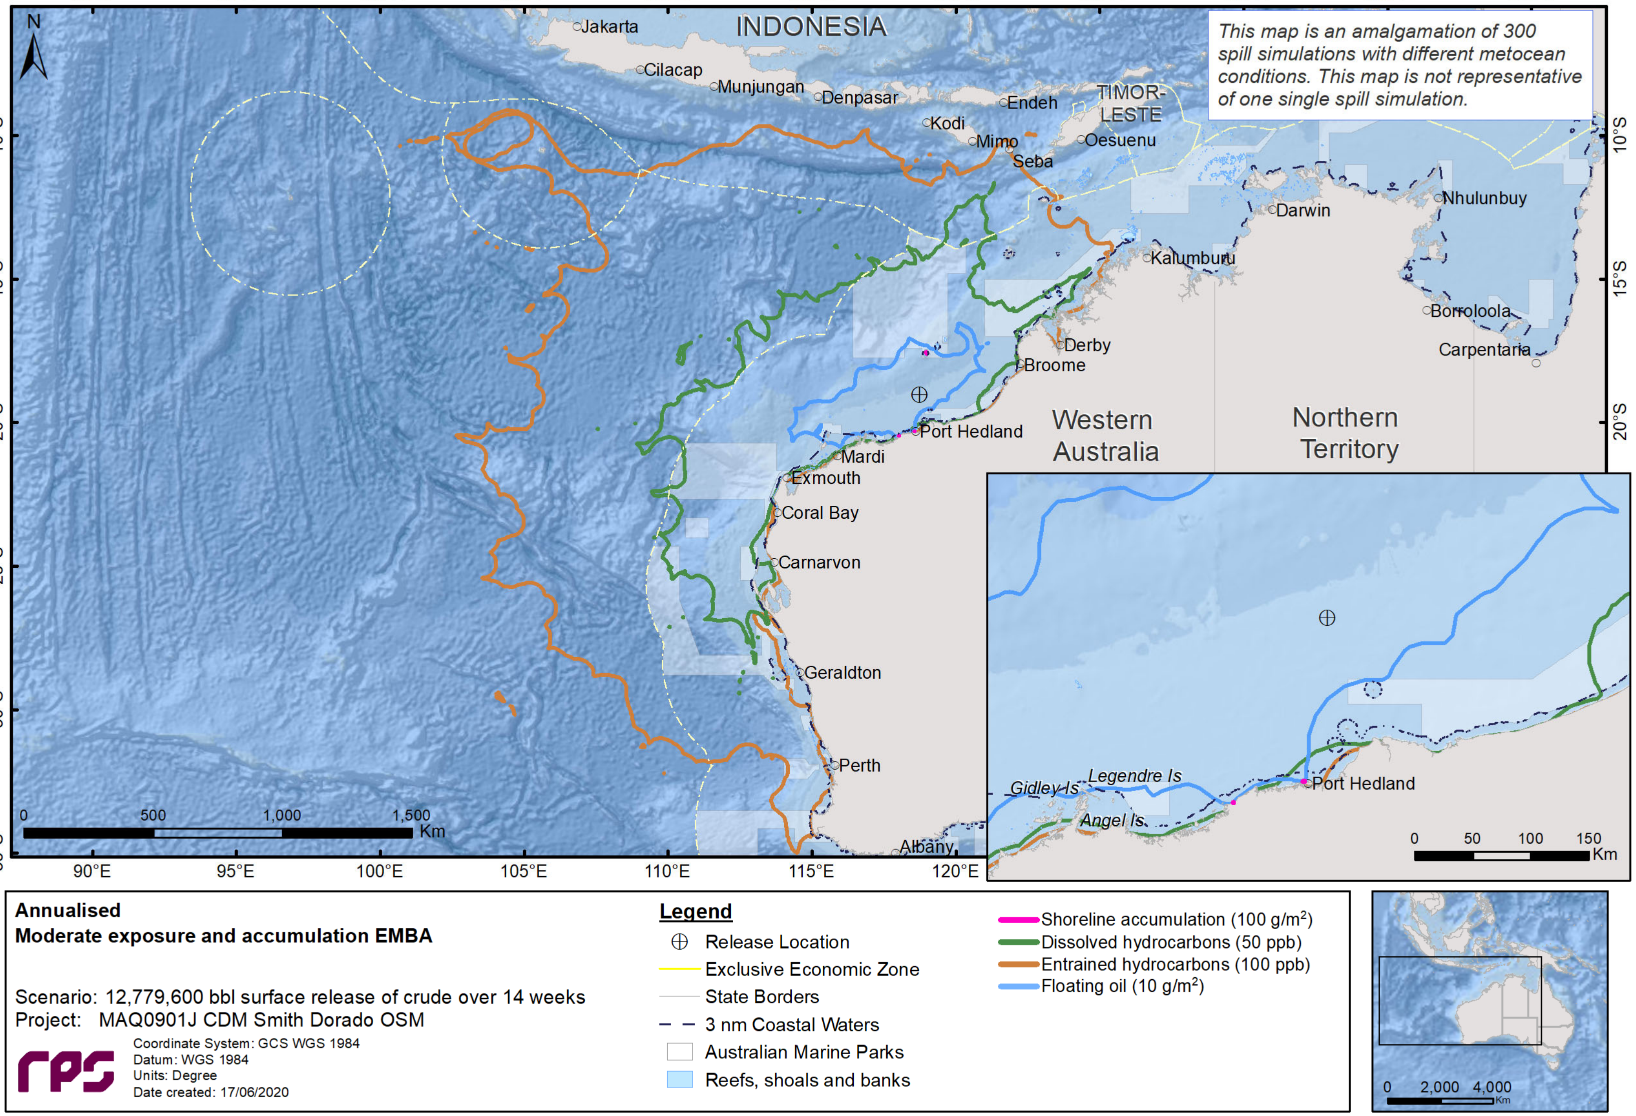

Figure 9.29 Annualised moderate threshold oil exposure and shoreline accumulation resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The annualised results were calculated from 300 spill simulations, which were tracked for 118 days.

9.2.2 Deterministic Analysis

The stochastic modelling results were assessed and the deterministic runs were identified and presented below based on the following criteria;

a. Largest volume of oil ashore; and

b. Longest length of oiled shoreline.

9.2.2.1 Deterministic Case: Largest volume of oil ashore

The deterministic simulation that recorded the largest volume of oil ashore (38.1 m^3) was identified during summer conditions as run number 40, which commenced at 6 am on the 24th of February 2018. The maximum volume ashore was 38.1 m^3, which occurred 44 days after the initial release.

Exposure from floating oil (swept area) and potential oil accumulation over the entire 118 day simulation are presented in Figure 9.30 and Figure 9.31, respectively. Floating oil exposure was predicted north/northeast and west/southwest from the release location with oil accumulation occurring at Port Hedland.

Figure 9.32 displays the time series of the area and length of visible oil (≥1 g/m^2) and actionable floating oil exposure on the sea surface (≥50 g/m^2) and actionable shoreline oil (≥100 g/m^2) over the 118-day simulation.

Figure 9.33 is a time series of the volume on shore at the low (10-100 g/m^2), moderate (100-1,000 g/m^2) and high (≥ 1,000 g/m^2) thresholds.

Figure 9.34 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 1,242,759 m^3 (61%) spilled oil was lost to the atmosphere through evaporation. Approximately 625,632 m^3 (31%) of the crude was predicted to have decayed, while 159,384 m^3 (8%) remained within the water column and 15 m^3 (<0.1%) was predicted to remain on the shoreline.

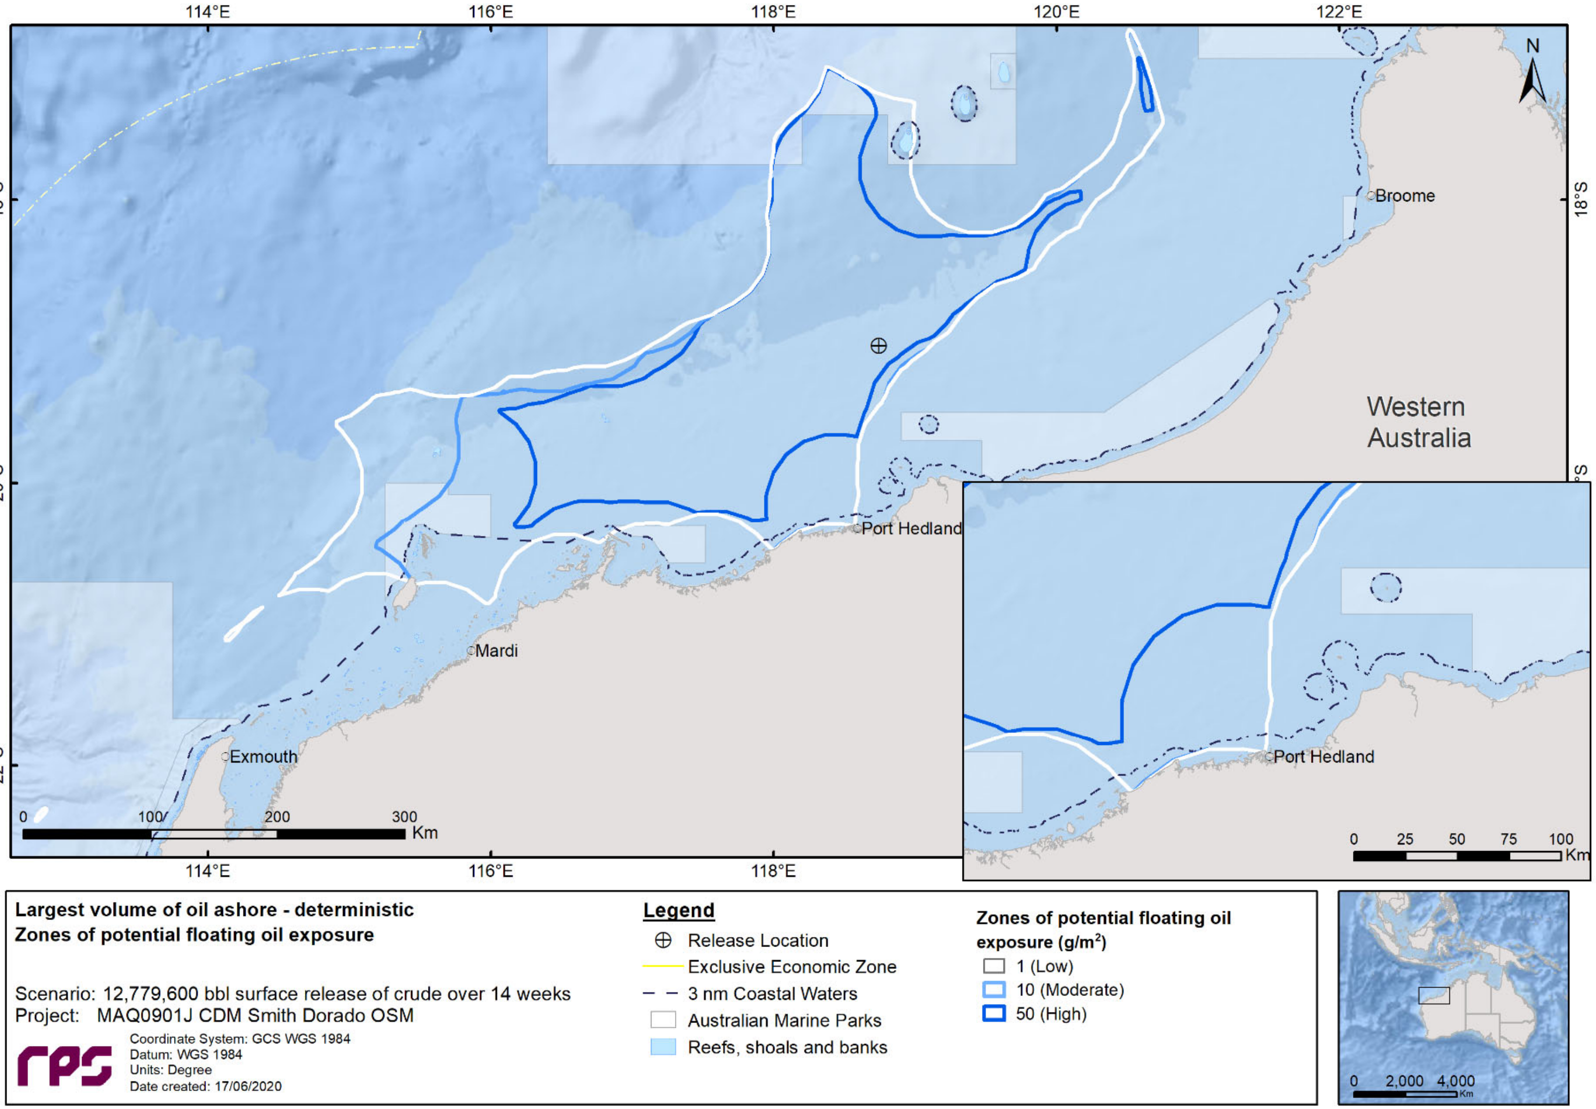

Figure 9.30 **Exposure from floating oil (over the 118 day simulation) for the simulation with the largest volume of oil ashore. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, starting 6 am on the 24th of February 2018.**

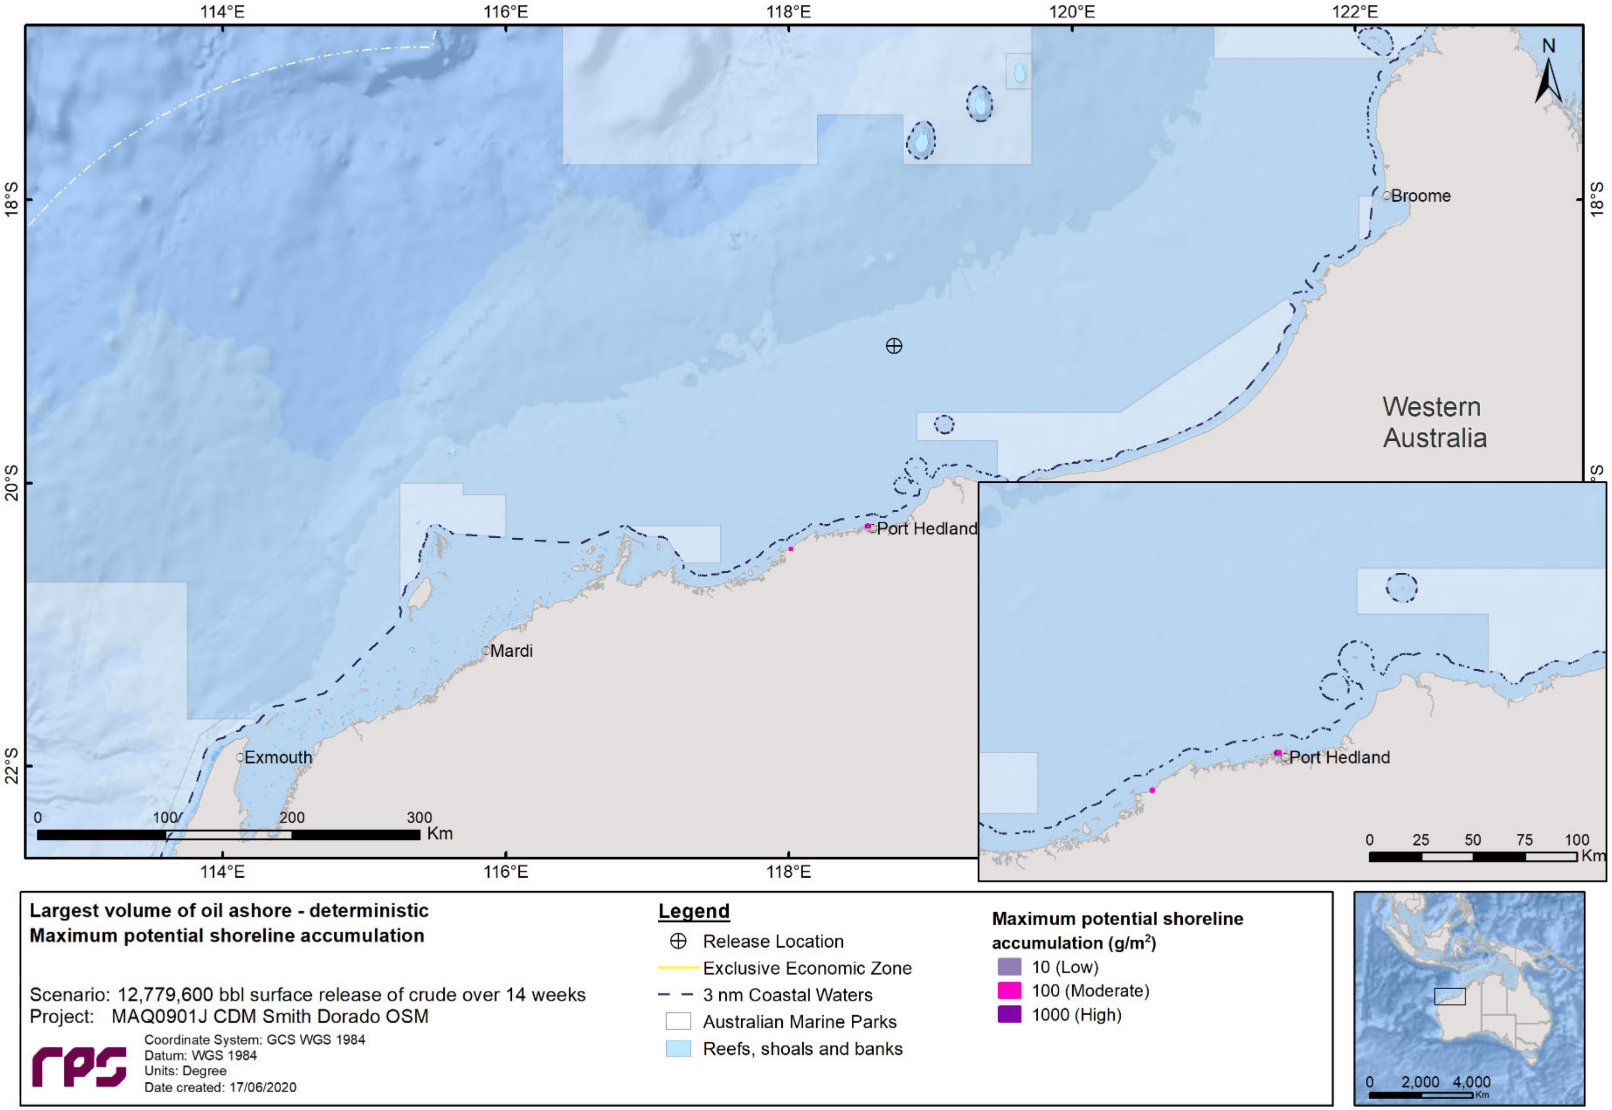

Figure 9.31 **Potential shoreline accumulation (over the 118 day simulation) for the simulation with the largest volume of oil ashore. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, starting 6 am on the 24th of February 2018.**

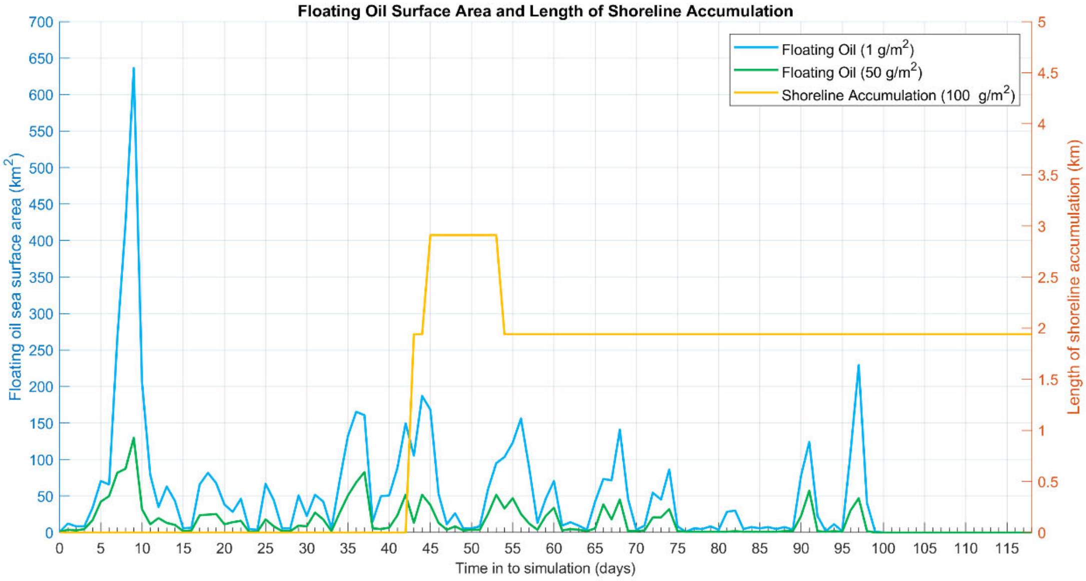

Figure 9.32 Time series of the area of visible (≥1 g/m²) and actionable floating oil (≥50 g/m²) on the sea surface and length of actionable shoreline oil (≥100 g/m²) for the simulation with the largest volume of oil ashore. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP, tracked for 118 days, 6 am on the 24th of February 2018.

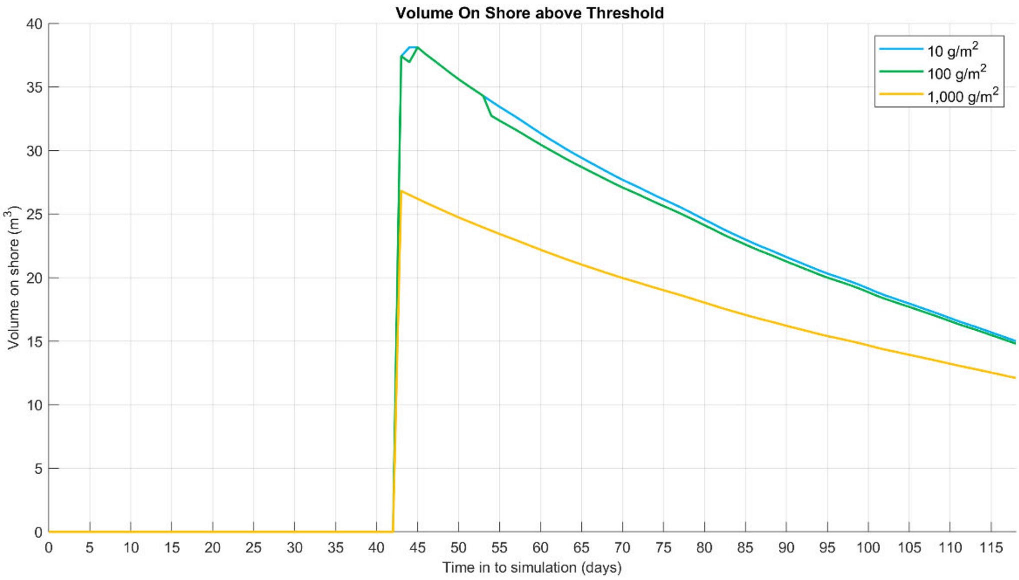

Figure 9.33 Time series of the volume on shore at the low (10-100 g/m²), moderate (100-1,000 g/m²) and high (≥ 1,000 g/m²) thresholds for the simulation with the largest volume of oil ashore. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP, tracked for 118 days, 6 am on the 24th of February 2018.

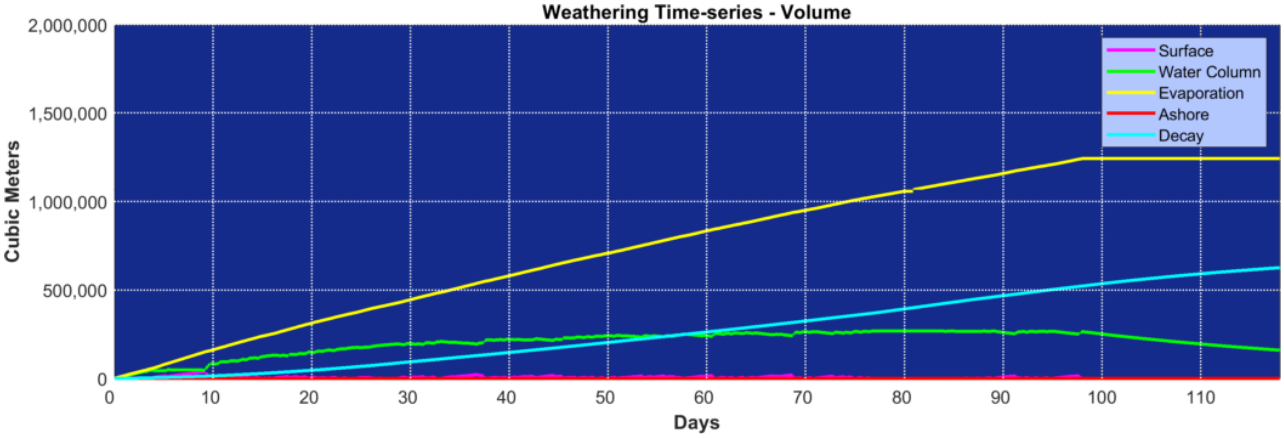

Figure 9.34 Predicted weathering and fates graph for the single spill simulation with the largest volume of oil ashore. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP, tracked for 118 days, 6 am on the 24th of February 2018.

9.2.2.2 Deterministic Case: Longest length of oiled shoreline

The deterministic simulation that resulted in the longest length of oiled shoreline 100 g/m^2 was identified during summer conditions as run number 21 which commenced at 9 pm on the 21st of January 2018.

Exposure from floating oil (swept area) and potential oil accumulation over the entire 118-day simulation are presented in Figure 9.35 and Figure 9.36, respectively. Floating oil exposure was predicted to occur northeast and west/southwest from the release location with shoreline accumulation occurring at the following sensitive shoreline receptors (refer Section 7.3) Port Hedland, Cunningham Island and Imperieuse Reef.

Figure 9.37 displays the time series of the area and length of visible oil (≥1 g/m^2) and actionable floating oil exposure on the sea surface (≥50 g/m^2) and actionable shoreline oil (≥100 g/m^2) over the 118-day simulation. The maximum area of coverage of visible oil on the sea surface was predicted to occur 42 days after the spill started and covered approximately 552 km^2. While the maximum length of actionable shoreline oiled (above 100 g/m^2) at any given time was 2 km, approximately 76 days into the simulation.

Figure 9.38 is a time series of the volume on shore at the low (10-100 g/m^2), moderate (100-1,000 g/m^2) and high (≥ 1,000 g/m^2) thresholds.

Figure 9.39 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 1,228,951 m^3 (60%) spilled oil was lost to the atmosphere through evaporation. Approximately 637,450 m^3 (31%) of the crude was predicted to have decayed, while 161,393 m^3 (8%) remained within the water column and 5 m^3 (<0.1%) was predicted to remain on the shoreline.

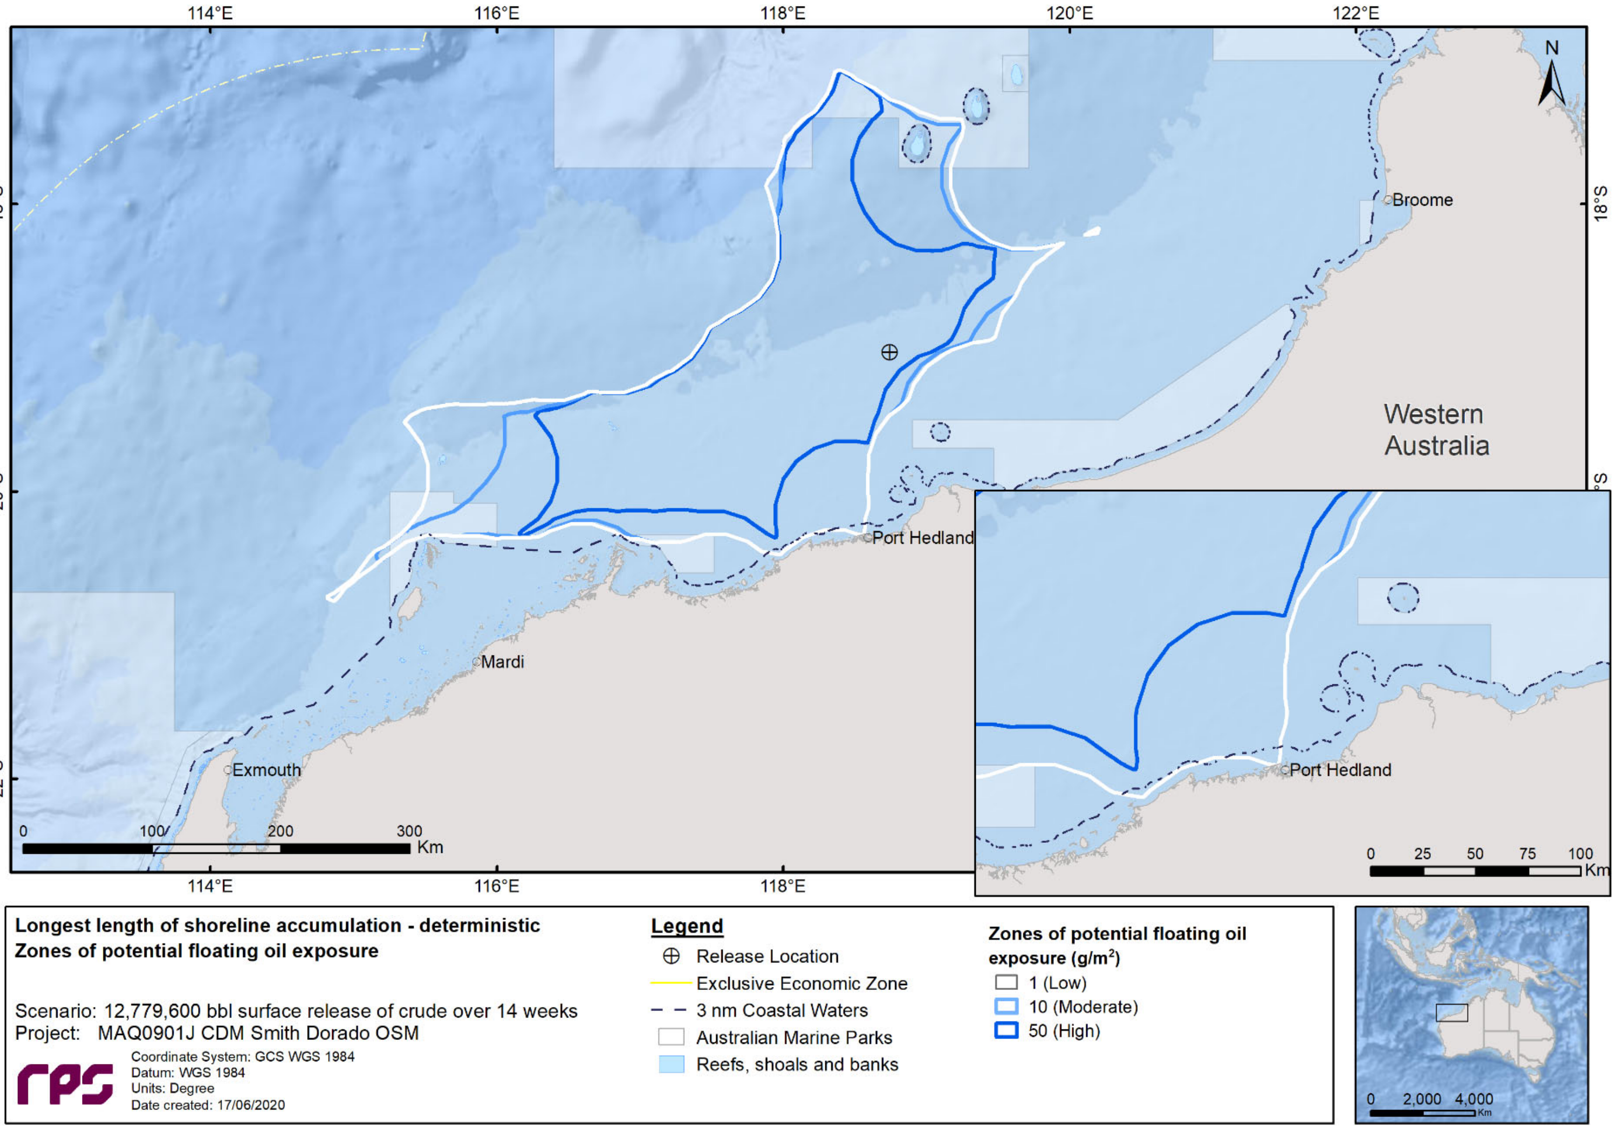

Figure 9.35 Exposure from floating oil (over the 118 day simulation) for the simulation with the longest length of shoreline with accumulation above 100 g/m^2. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, starting 9 pm on the 21st of January 2018.

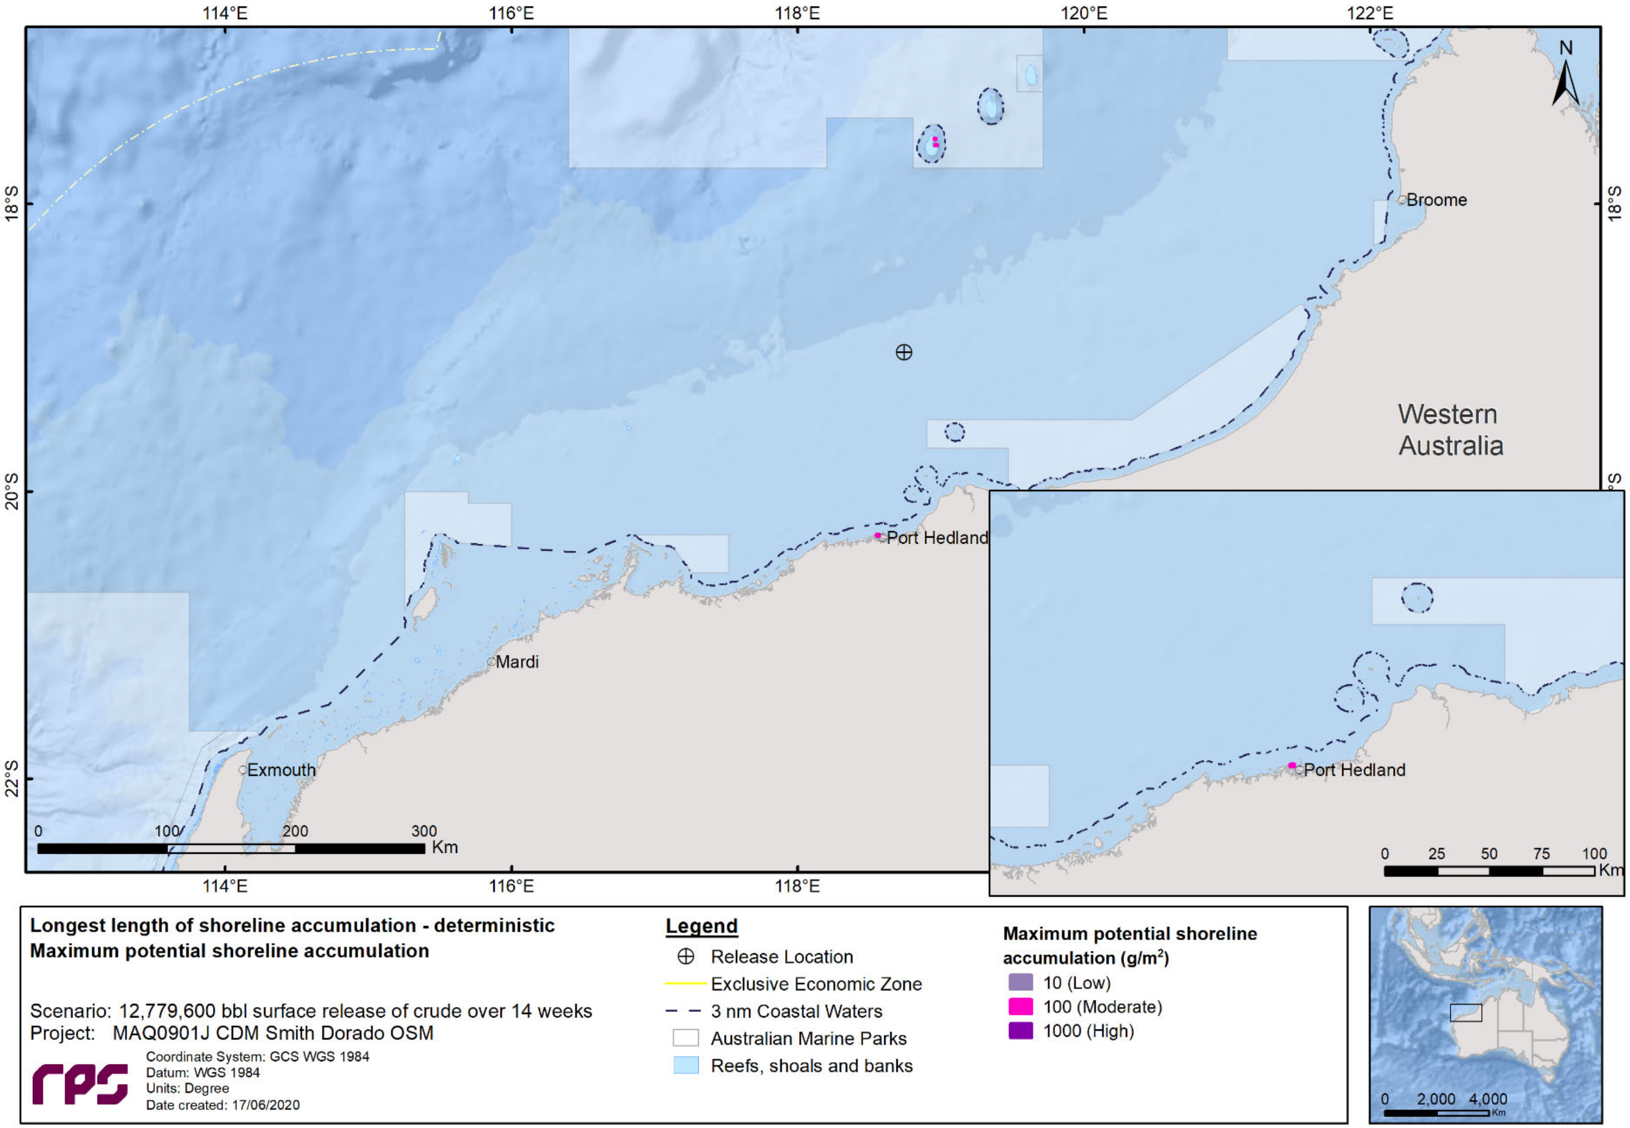

Figure 9.36 Potential shoreline accumulation (over the 118 day simulation) for the simulation with the longest length of shoreline with accumulation above 100 g/m^2. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, starting 9 pm on the 21st of January 2018.

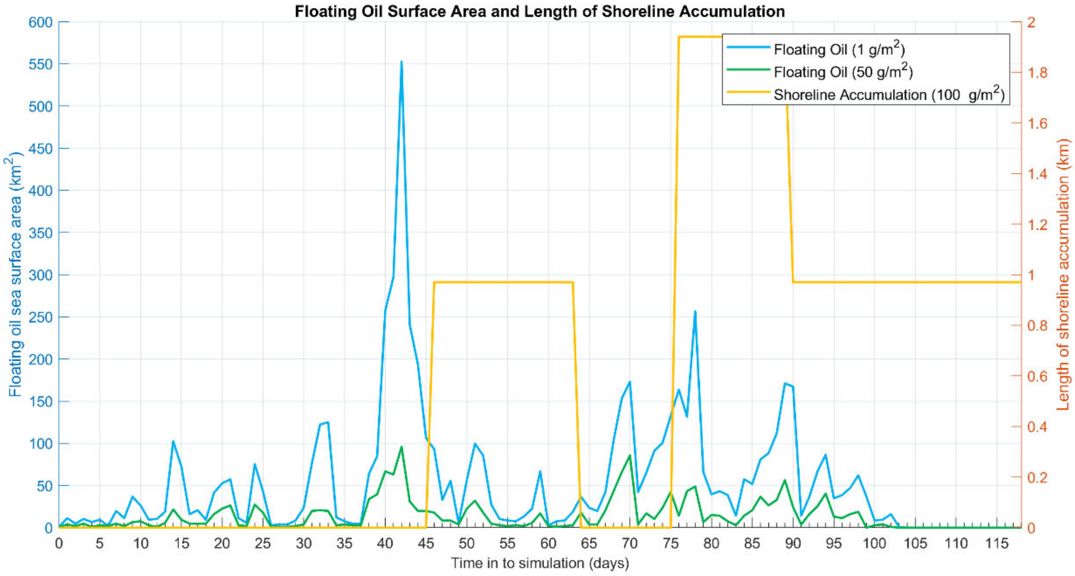

Figure 9.37 Time series of the area of visible (≥1 g/m^2) and actionable floating oil (≥50 g/m^2) on the sea surface and length of actionable shoreline oil (≥100 g/m^2) for the simulation with the longest length of shoreline with accumulation above 100 g/m^2. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, tracked for 118 days, 9 pm on the 21st of January 2018.

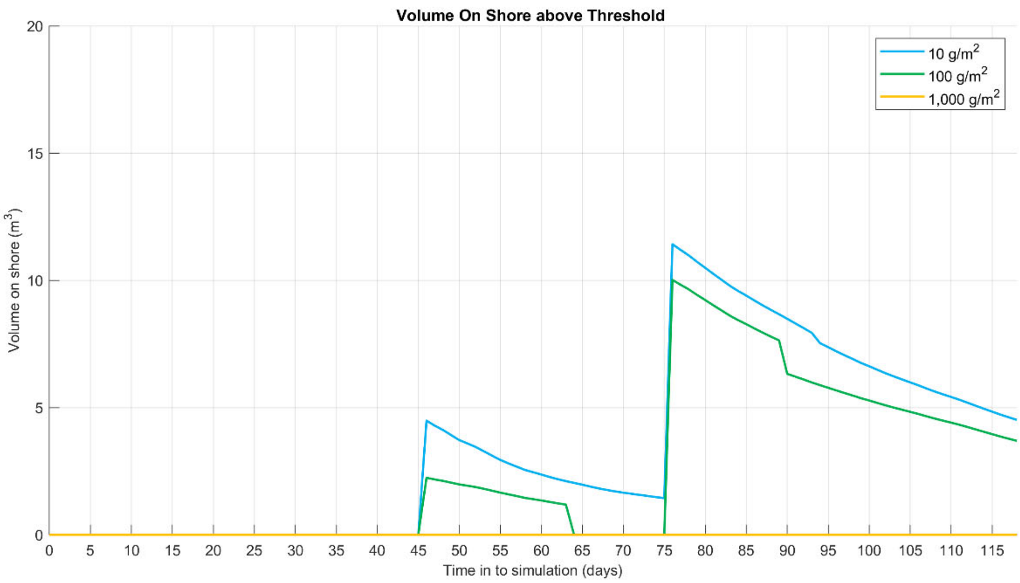

Figure 9.38 Time series of the volume on shore at the low (10-100 g/m^2), moderate (100-1,000 g/m^2) and high (≥ 1,000 g/m^2) thresholds for the simulation with the longest length of shoreline with accumulation above 100 g/m^2. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, tracked for 118 days, 9 pm on the 21st of January 2018.

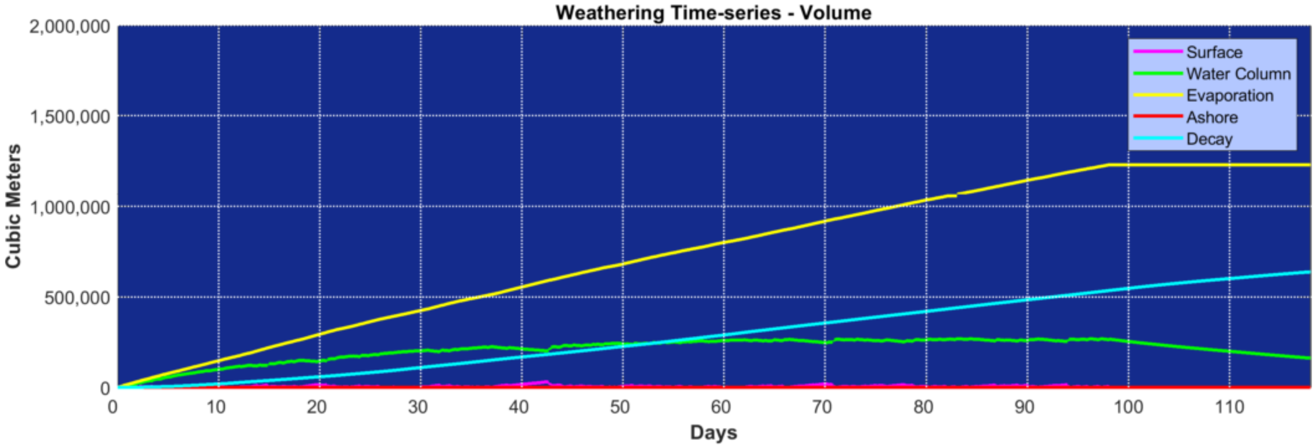

Figure 9.39 Predicted weathering and fates graph for the single spill simulation with the longest length of shoreline with accumulation above 100 g/m^2. Results are based a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP, tracked for 118 days, 9 pm on the 21st of January 2018.

9.2.3 Seasonal analysis

9.2.3.1 Floating Oil Exposure

Table 9.14 summarises the maximum distances from the release location to floating oil exposure zones for each season. The maximum distance from the release location to the low (1–10 g/m^2), moderate (10–50 g/m^2) and high (≥ 50 g/m^2) exposure thresholds was 1,201.9 km southwest (summer), 497.3 km west-southwest (transitional) and 304.5 km west-southwest (summer and transitional), respectively.

Images of floating oil exposure zones are depicted in Figure 9.40, Figure 9.41 and Figure 9.42 for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively.

Table 9.15 to Table 9.17 summarise the potential floating oil exposure to individual receptors for each season, based on combining the results of the 100 simulations. Within the predicted exposure zone from the combined season simulations, there are 7 AMPs, 6 during summer, 1 during transitional and 4 for winter conditions. Montebello AMP recorded the highest probability of exposure to floating oil at 18% during summer conditions. The shortest time for floating oil at the low threshold to reach an AMP was recorded at Argo-Rowley Terrace as 7.50 days during summer conditions.

There are 3 RSBs within the predicted zone of floating oil exposure (at the low threshold) and Imperieuse Reef recorded the highest probability at 9% during summer conditions and the quickest time before exposure of 12.88 days.

Low (1-10 g/m^2) floating oil was predicted to cross into WA State Waters during every season with probabilities ranging from 1-12%. The minimum time before oil crossed the WA State Waters boundary was 2.83 days recorded for a spill commencing during transitional conditions.

Table 9.14 Maximum distance and direction from the release location to floating oil exposure thresholds. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations per season.

Season	Distance and direction	Exposure from floating oil		
		Low (1-10 g/m^2)	Moderate (10-50 g/m^2)	High (≥50 g/m^2)
Summer	Max. distance from release site (km)	1201.9	407.4	304.5
	Max distance from release site (km) (99th percentile)	1044.2	303.3	217.1
	Direction	Southwest	West-Southwest	West-Southwest
Transitional	Max. distance from release site (km)	508.2	497.3	304.5
	Max distance from release site (km) (99th percentile)	399.6	342.2	251.9
	Direction	West-Southwest	West-Southwest	West-Southwest
Winter	Max. distance from release site (km)	413.8	375.9	221.7
	Max distance from release site (km) (99th percentile)	304.4	257.8	152.5
	Direction	Northeast	Northeast	Northeast

Table 9.15 Summary of the potential floating oil exposure to individual receptors. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP during summer (October to March) conditions. The results were calculated from 100 spill simulations.

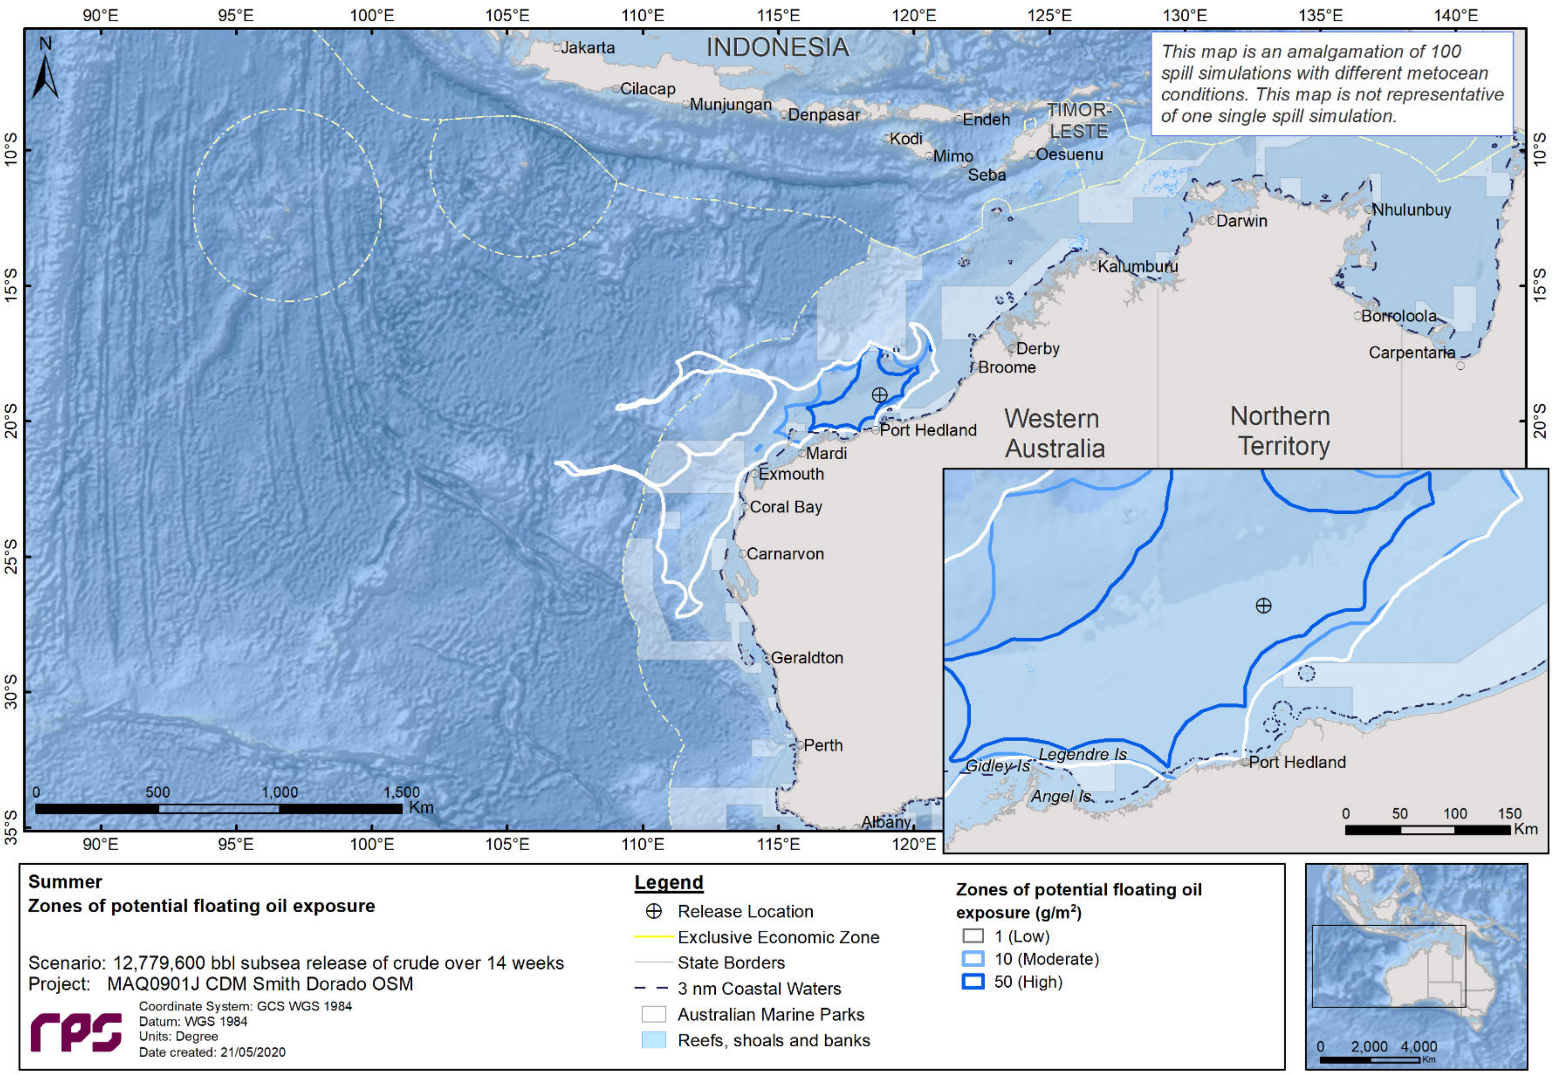

Figure 9.40 Predicted floating oil exposure zones resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

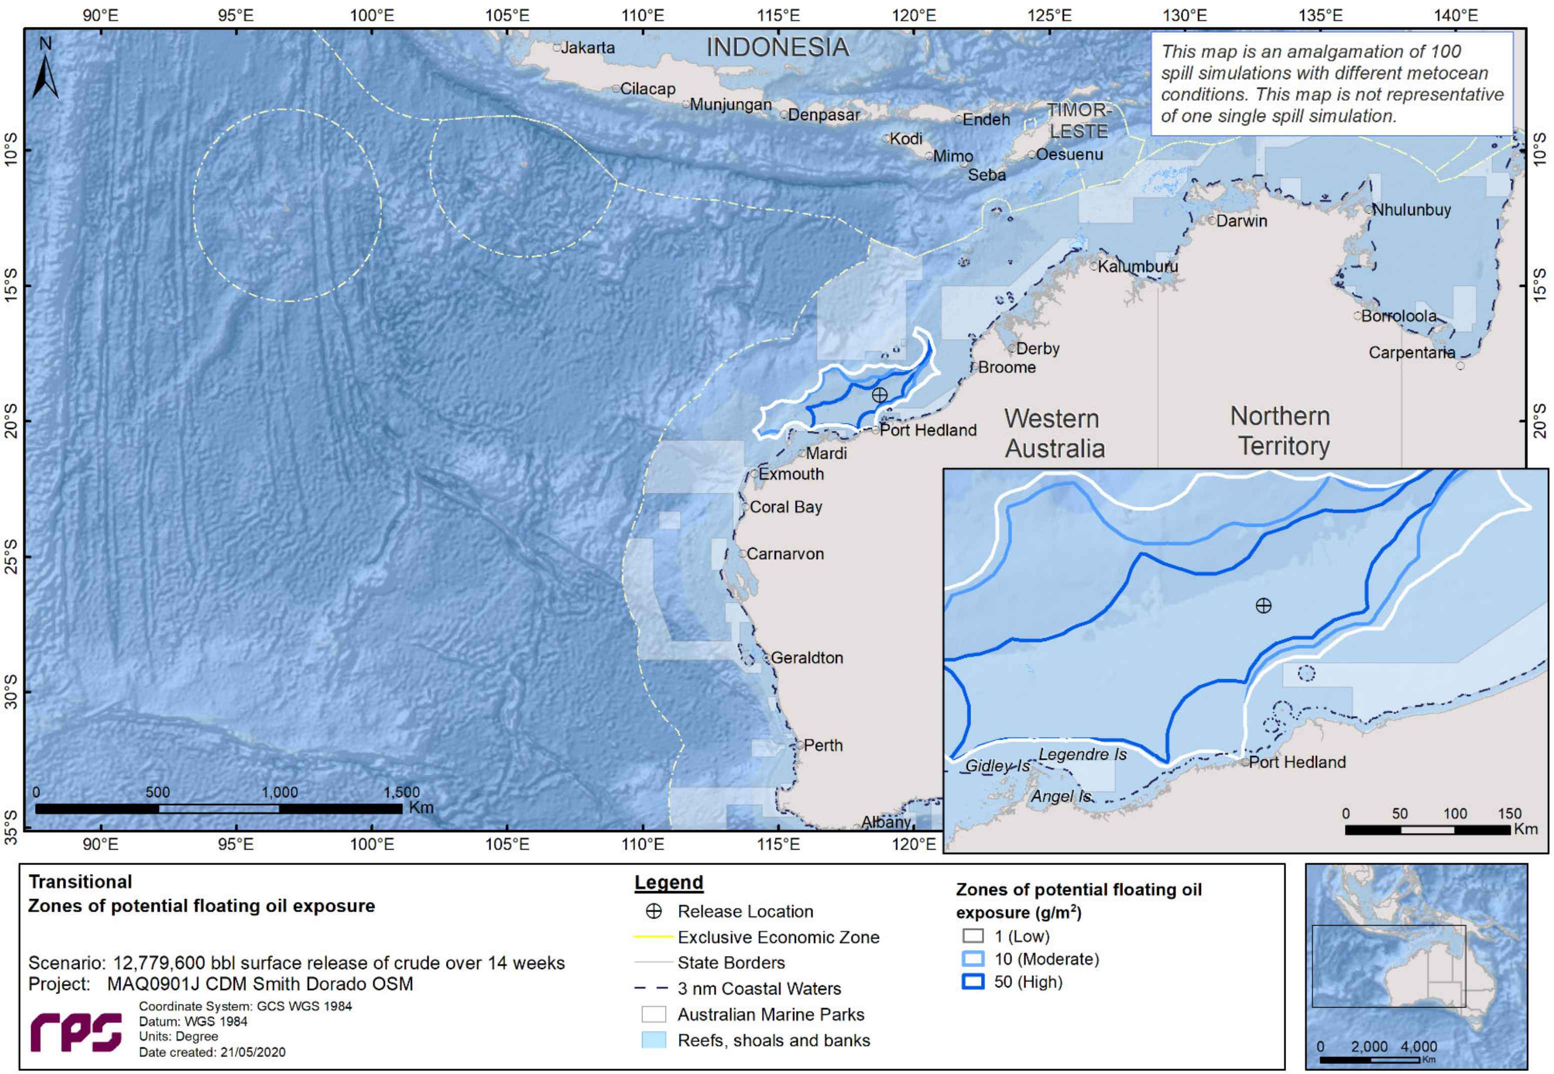

Figure 9.41 Predicted floating oil exposure zones resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

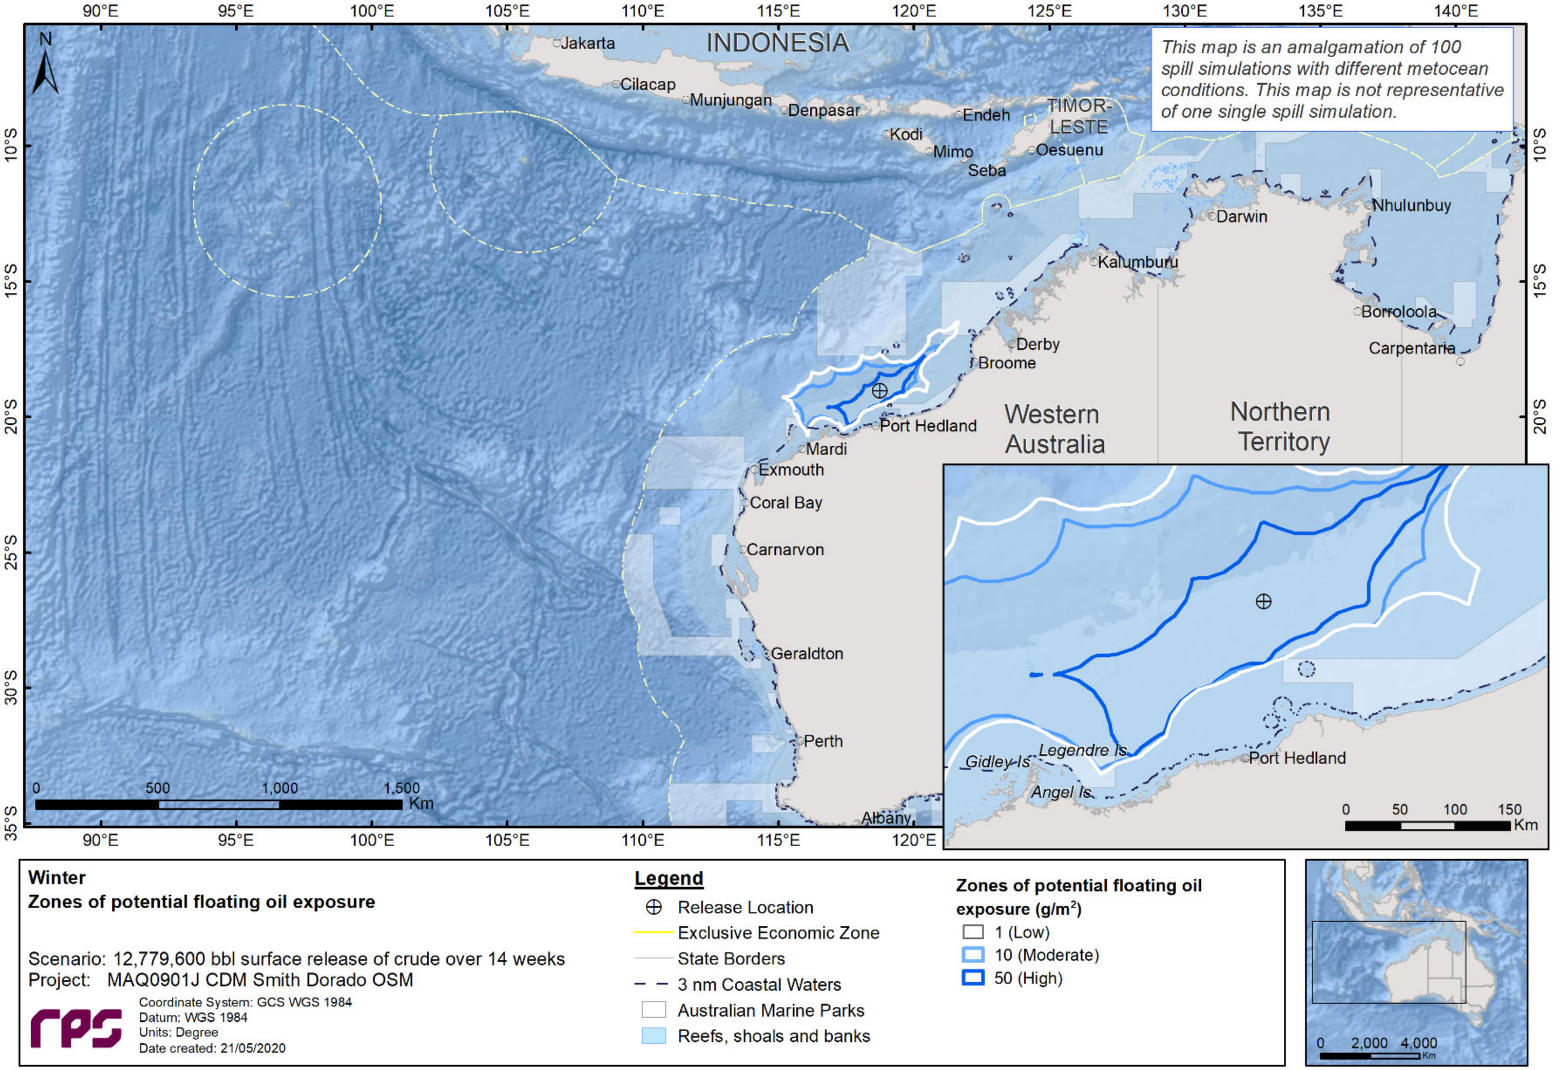

Figure 9.42 Predicted floating oil exposure zones exposure resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.2.3.2 Shoreline Accumulation

Table 9.18 presents a summary of the predicted oil accumulation on any shoreline for all three seasons assessed. The probability of oil accumulation at, or above, the low threshold (10-100 g/m^2) during the summer and transitional seasons was 11% and 1%, respectively. The minimum time before oil accumulation above the low threshold was approximately 11.63 days and 2.88 days, respectively. The greatest volume of oil ashore was 38.1 m^3 and 10 m^3 during summer and transitional conditions, respectively. There was no oil accumulation on any shoreline above the low threshold predicted for spills commencing during winter conditions.

Table 9.19 and Table 9.20 summarise the oil accumulation on individual sensitive shoreline receptors assessed for summer and transitional conditions. Based on combining 100 simulations per season, oil was predicted to accumulate on 3 shoreline receptors at, or above, the low threshold (10-100 g/m^2) during summer and only 1 receptor (Port Hedland) during transitional conditions. Port Hedland recorded the highest probability of oil accumulation at the low threshold (9%) during summer conditions, while the quickest time before soil accumulation was predicted during transitional conditions as 2.88 days. The greatest potential volume of oil ashore was 38.1 m^3 and the maximum length of shoreline predicted to have accumulation at the low threshold was 3 km, both occurring at Port Hedland during summer conditions.

The maximum potential shoreline loading at low, moderate and high accumulation thresholds are depicted in Figure 9.43 and Figure 9.44 based on the 100 spill simulations commencing during summer and transitional conditions, respectively.

Table 9.18 Summary of oil accumulation on any shoreline. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during all seasonal conditions. The results were calculated from 100 spill simulations per season.

Shoreline Statistics	Summer	Transitional	Winter
Probability of shoreline accumulation at, or above **10 g/m^2** (%)	11.0	1.0	-
Minimum time before shoreline accumulation at, or above **10 g/m^2** (days)	11.6	2.9	-
Maximum volume of oil ashore (m^3) from a single simulation	38.1	10.0	-
Average volume of oil ashore (m^3)	17.3	10.0	-
Maximum length of shoreline accumulation at or above **10 g/m^2** (km) from a single simulation	6.0	1.0	-
Average length of shoreline accumulation at or above **10 g/m^2** (km)	2.4	1.0	-
Maximum length of shoreline accumulation at or above **100 g/m^2** (km) from a single simulation	4.0	1.0	-
Average length of shoreline accumulation at or above **100 g/m^2** (km)	2.1	1.0	-
Maximum length of shoreline accumulation at or above **1,000 g/m^2** (km) from a single simulation	2.0	-	-
Average length of shoreline accumulation at or above **1,000 g/m^2** (km) for all simulations predicted to reach the shorelines	1.2	-	-

Table 9.19 Summary of oil accumulation on individual shorelines. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Shoreline receptor	Maximum probability of shoreline accumulation (%)			Minimum time before shoreline accumulation (days)			Load on shoreline (g/m²)		Volume on shoreline (m³)		Mean length of shoreline accumulation (km)			Maximum length of shoreline accumulation (km)

Port Hedland	1	1	-	2.9	2.9	-	854.1	854.1	0.1	10.0	1.0	1.0	-	1.0	1.0	-

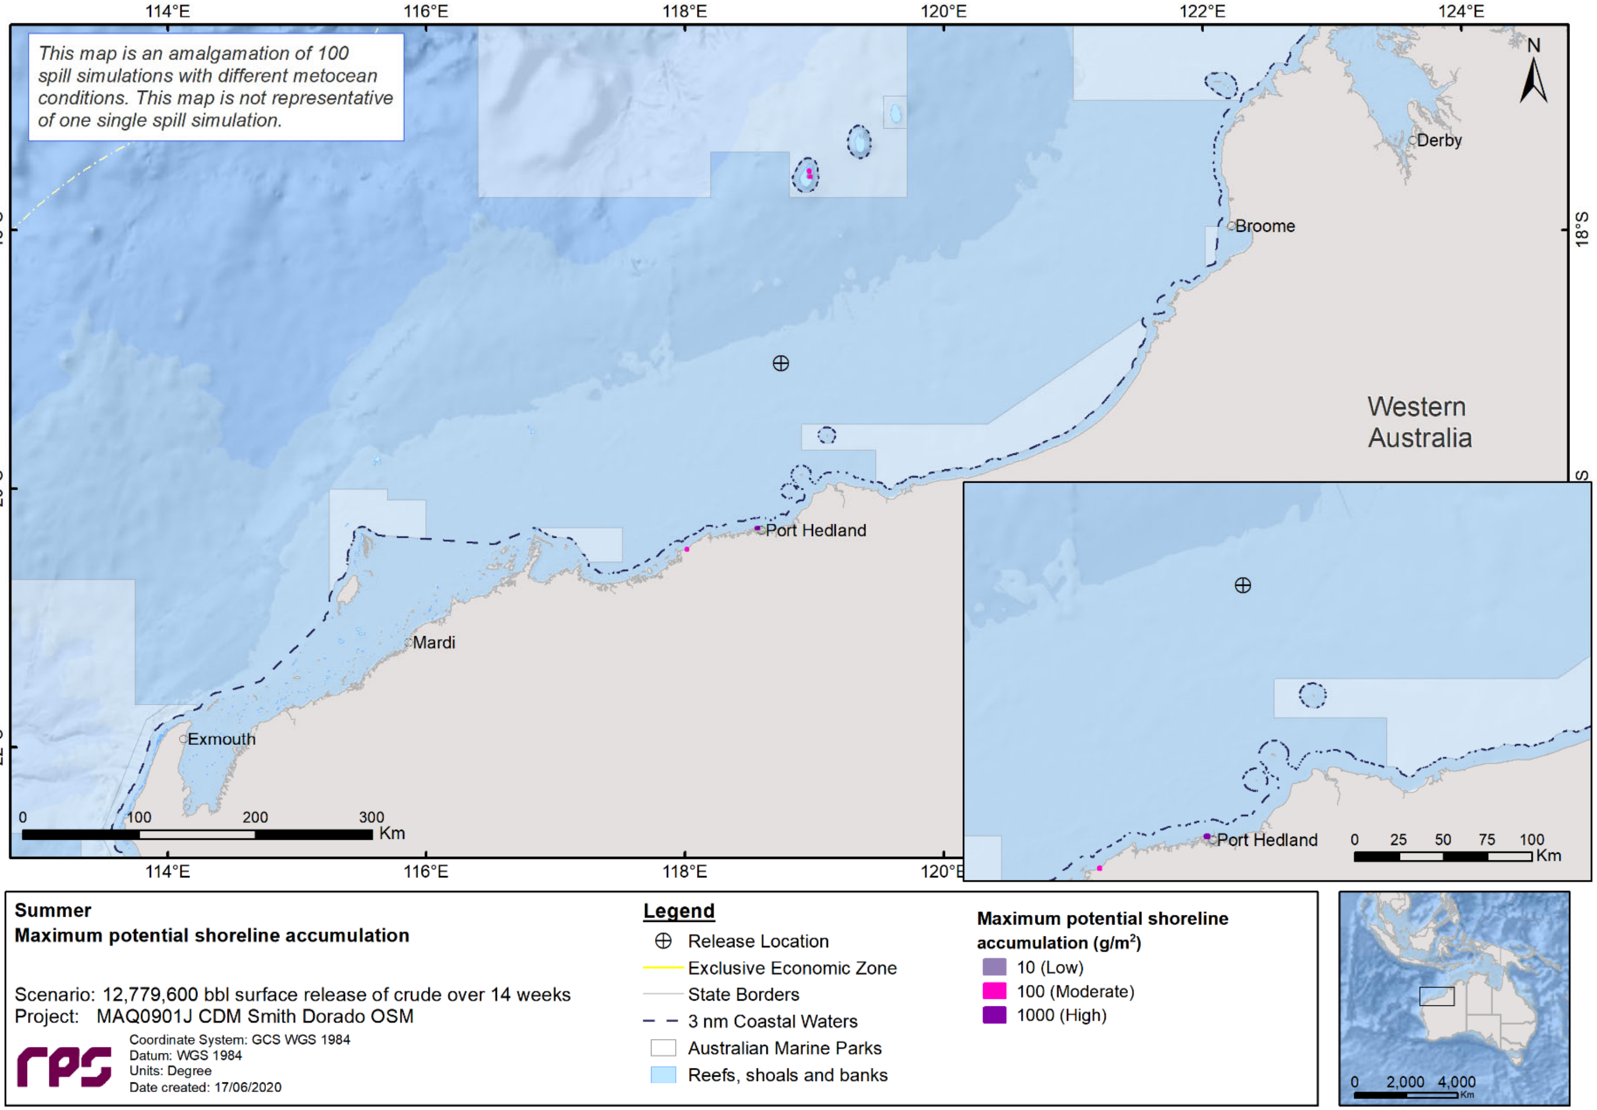

Figure 9.43 Predicted maximum shoreline accumulation resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

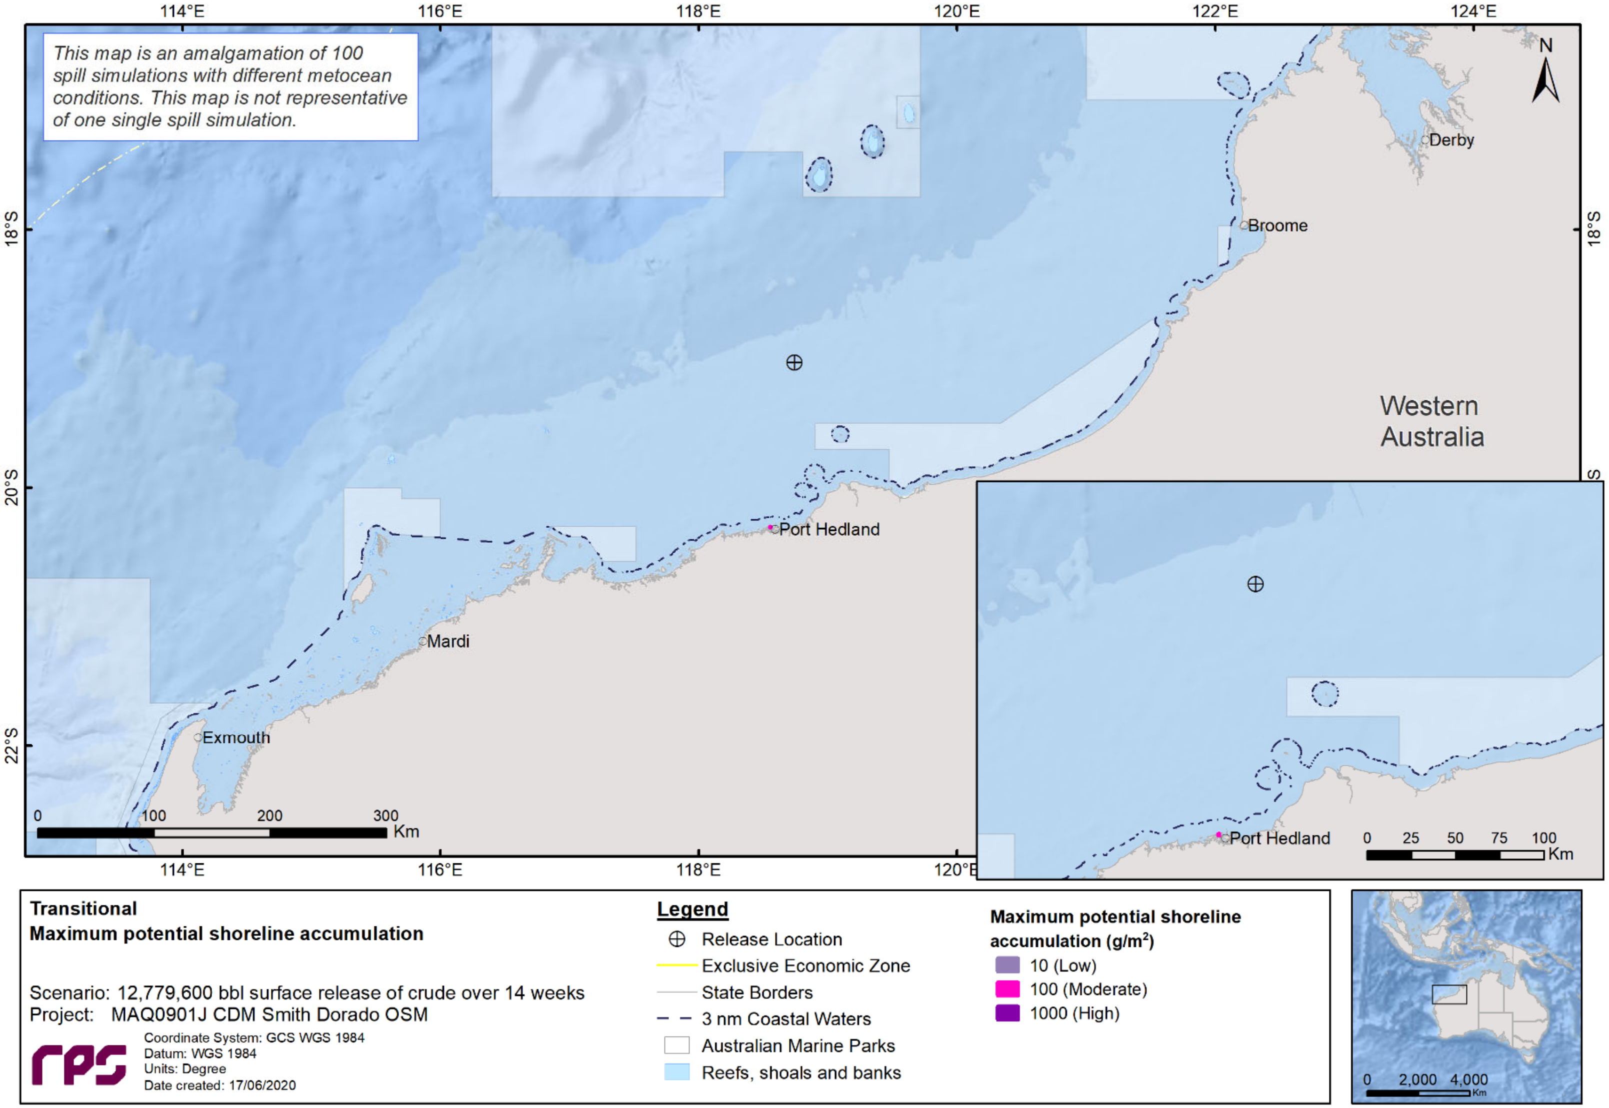

Figure 9.44 Predicted maximum shoreline accumulation resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

9.2.3.3 Entrained Hydrocarbons

Images of the entrained hydrocarbon exposure zones in the 0-10 m depth layer are depicted in Figure 9.45 , Figure 9.46 and Figure 9.47 for the combined 100 spill simulations each commencing during summer, transitional and winter conditions, respectively. The results indicated that exposure at the low threshold was predicted to occur up to a maximum distance of 2,932 km (west-northwest) from the spill site during winter conditions. This distance reduced to 2,169 km (west-northwest) as the threshold increased to moderate in winter conditions. The maximum distances for summer and transitional conditions at the low threshold were 2,600 km and 2,488 m, respectively. The maximum distances at the moderate threshold were reduced for summer (1,994 km) and transitional (1,753 km).

Table 9.21 to Table 9.23 summarise the probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer for each season. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at the shallowest depth from the sea surface for each KEF (representing the maximum concentrations).

There are 20 AMPs each within the low exposure zone for summer and transitional results and 19 AMPs within the zone based on winter conditions. Montebello AMP recorded the highest probability of exposure during summer (95%), while Argo Rowley AMP had the highest probabilities for transitional (96%) and winter (100%). The shortest time for entrained hydrocarbons at the low threshold (10-100 ppb) to contact an AMP was recorded at Dampier during transitional conditions as 2.63 days before exposure.

A total of 3 KEFs are within the low exposure zone across the cumulative envelope for the 3 seasons. The Houtman Abrolhos Islands and surrounding reefs KEF recorded the highest probability of exposure at the low threshold during all three seasons (12- 23%).

The number of RSB receptors within the low exposure zone varied from 75 in winter to 104 in summer conditions. The highest probability of exposure was predicted at Rankin Bank during all three seasons (summer 96%; transitional 94% and winter 97%). The quickest time for entrained hydrocarbons at the low threshold to reach an RSB receptor was predicted at Madeleine Shoals (4 days during transitional conditions).

Entrained hydrocarbons at the low threshold were predicted to cross into WA State Waters during every season with probabilities ranging from 81-93%. The minimum time before oil crossed the WA State Waters boundary was 2.71 days, for a spill commencing during transitional conditions.

Table 9.21 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Table 9.22 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during transitional (April and September) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of entrained hydrocarbon exposure		Minimum time (days) before hydrocarbon exposure at any depth		Maximum entrained hydrocarbon concentration (ppb)
		Low (10-100 ppb)	Moderate (≥ 100 ppb)	Low (10-100 ppb)	Moderate (≥ 100 ppb)	for a single simulation at any depth

Table 9.23 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during winter (May to August) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of entrained hydrocarbon exposure		Minimum time (days) before hydrocarbon exposure at any depth		Maximum entrained hydrocarbon concentration (ppb)
		Low (10-100 ppb)	Moderate (≥ 100 ppb)	Low (10-100 ppb)	Moderate (≥ 100 ppb)	for a single simulation at any depth

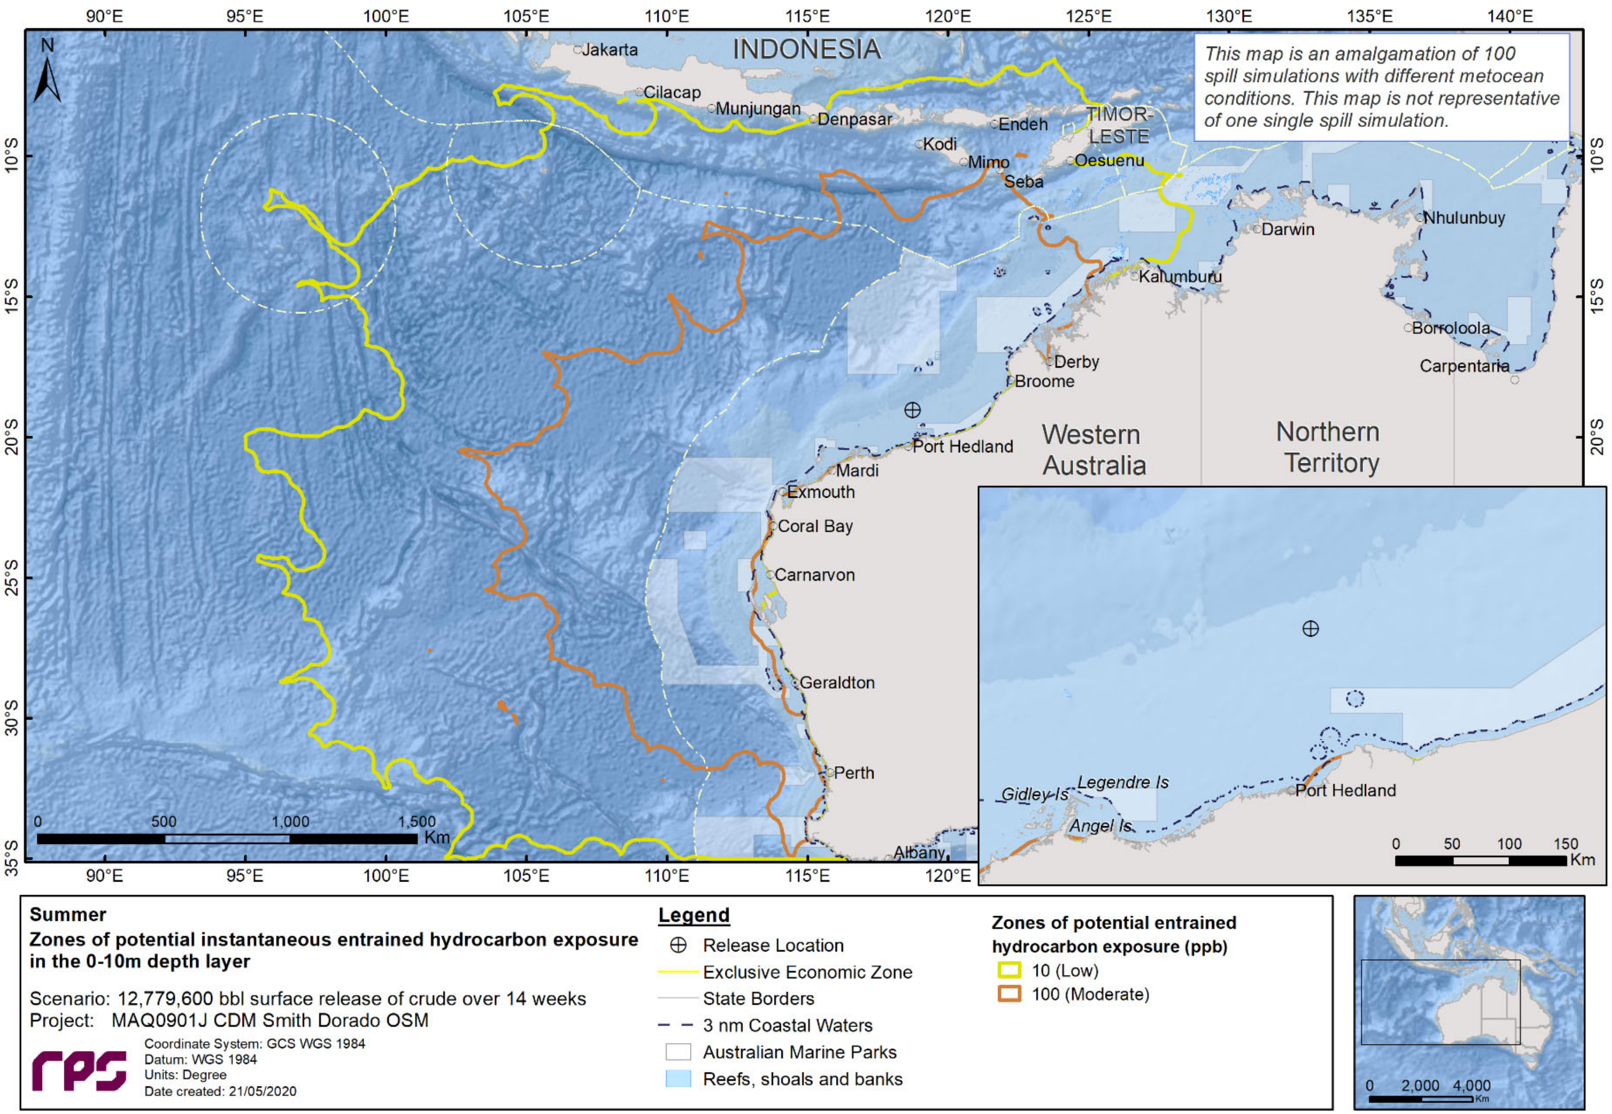

Figure 9.45 Predicted entrained hydrocarbon exposure zones resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

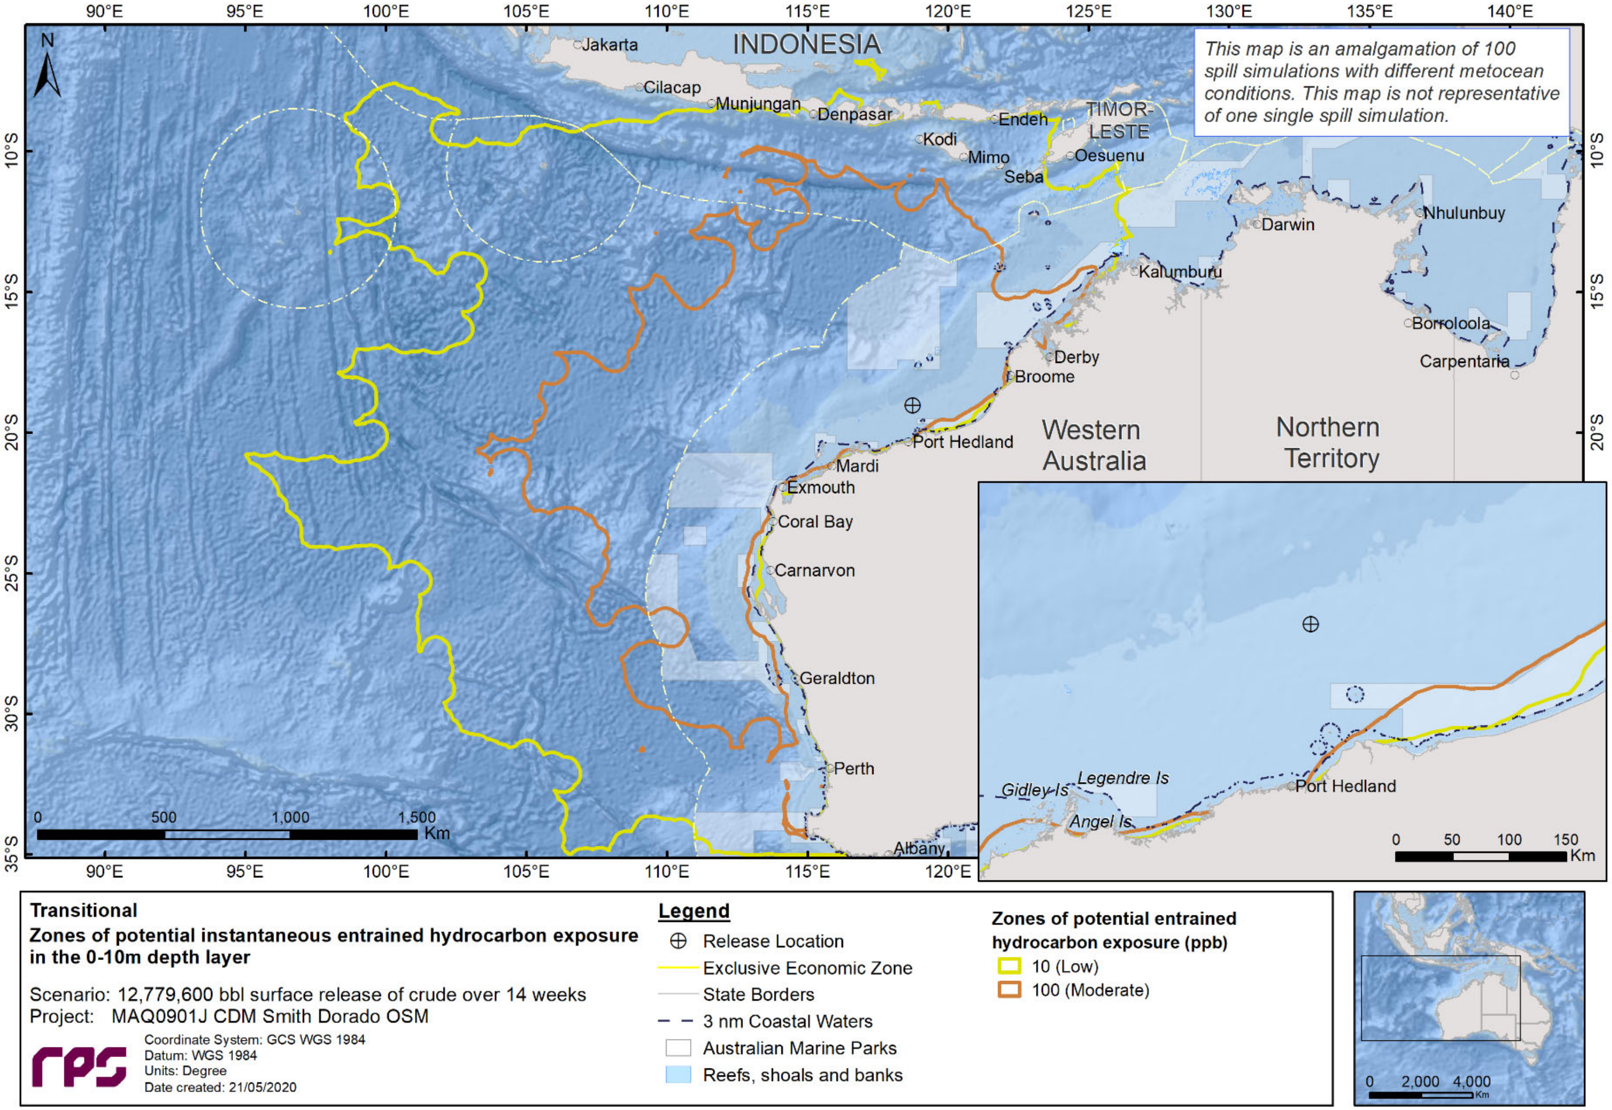

Figure 9.46 Predicted entrained hydrocarbon exposure zones resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

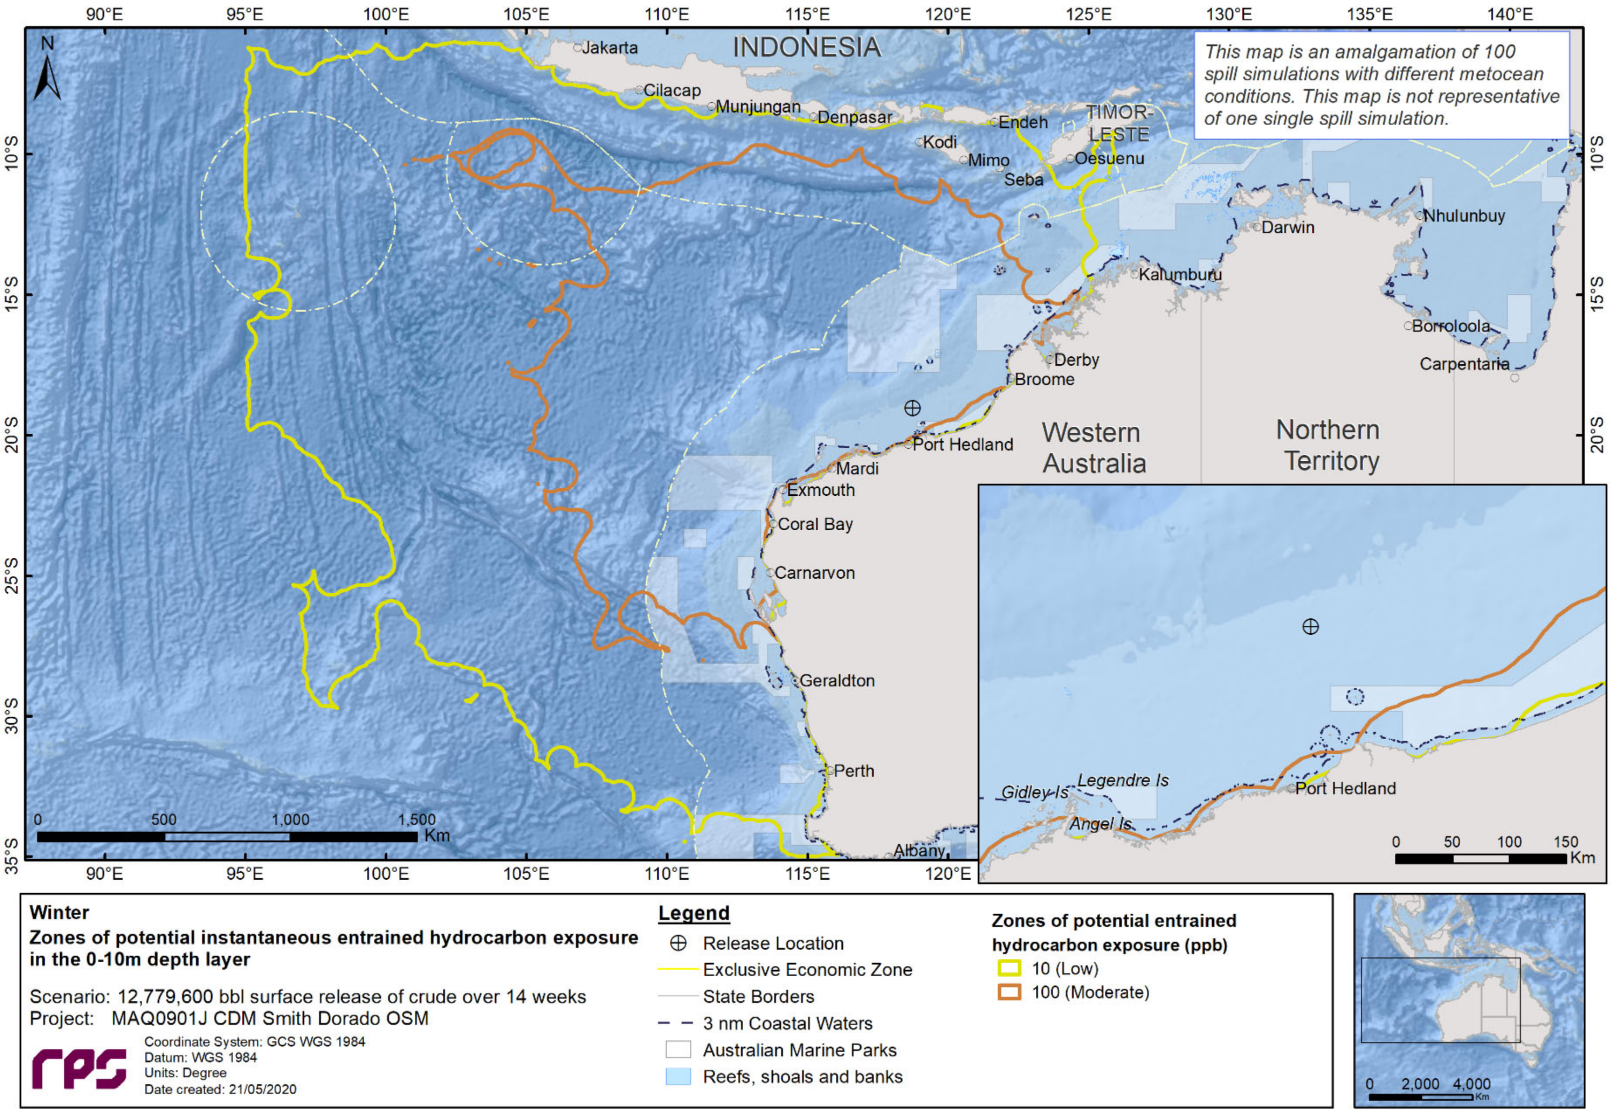

Figure 9.47 Predicted entrained hydrocarbon exposure zones resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.2.3.4 Dissolved Hydrocarbons

Images of dissolved hydrocarbon exposure zones are depicted in Figure 9.48, Figure 9.49 and Figure 9.50. for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively. The maximum distance from the spill site to the low exposure threshold (10-50 ppb) for summer, transitional and winter results were 1,509 km (west-southwest), 1,334 km (west southwest) and 1,334 km (west), respectively. This distance reduced to 1,265 km (southwest; summer), 1,117 km (west southwest; transitional) and 1,181 km (west; winter) as the threshold increased to moderate (50 – 400 ppb). Based on the high threshold (≥400 ppb) the distance reduced further to 892 km (west southwest; summer), 509 km (west; transitional) and 975 km (southwest; winter).

Table 9.24 to Table 9.26 summarise the probability of exposure to receptors from instantaneous dissolved hydrocarbons in the 0-10 m depth layer. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at their shallowest depth from the sea surface.

The low exposure zone surrounded 12 AMPs during summer conditions, 11 for transitional and winter conditions. The Argo-Rowley Terrace AMP recorded the highest probability of exposure at 78% during winter conditions. The shortest time for exposure at low threshold to an AMP was recorded at Dampier during transitional conditions as 2.67 days.

Three KEFs are within the low exposure zone for summer conditions and two during transitional conditions. There were no KEFs exposed during winter conditions. Commonwealth waters adjacent to Ningaloo Reef KEF recorded the highest probability of exposure at the low threshold during summer conditions (24%), while Western rock lobster recorded a 2% probability during transitional conditions.

Across the 3 seasons, there are 42 RSBs with the low exposure zone. The highest probability of exposure predicted at Rankin Shoal during summer conditions (70%). The shortest time before low exposure at an RSB receptor was 3.96 days at Madeleine Shoals during transitional conditions.

Dissolved hydrocarbons at the low threshold were predicted to cross into WA State Waters during every season with probabilities ranging from 39-64%. The minimum time before dissolved hydrocarbons at the low threshold crossed the WA State Waters boundary was 2.88 days, for a spill commencing during transitional conditions.

Table 9.24 Probability of exposure to individual receptors from instantaneous dissolved hydrocarbons in the 0-10 m depth layer. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of dissolved hydrocarbon exposure			Minimum time (days) before hydrocarbon exposure at any depth			Maximum dissolved hydrocarbon concentration (ppb)

Table 9.25 Probability of exposure to individual receptors from instantaneous dissolved hydrocarbons in the 0-10 m depth layer. Results are based on a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP during transitional (April and September) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of dissolved hydrocarbon exposure			Minimum time (days) before hydrocarbon exposure at any depth			Maximum dissolved hydrocarbon concentration (ppb)

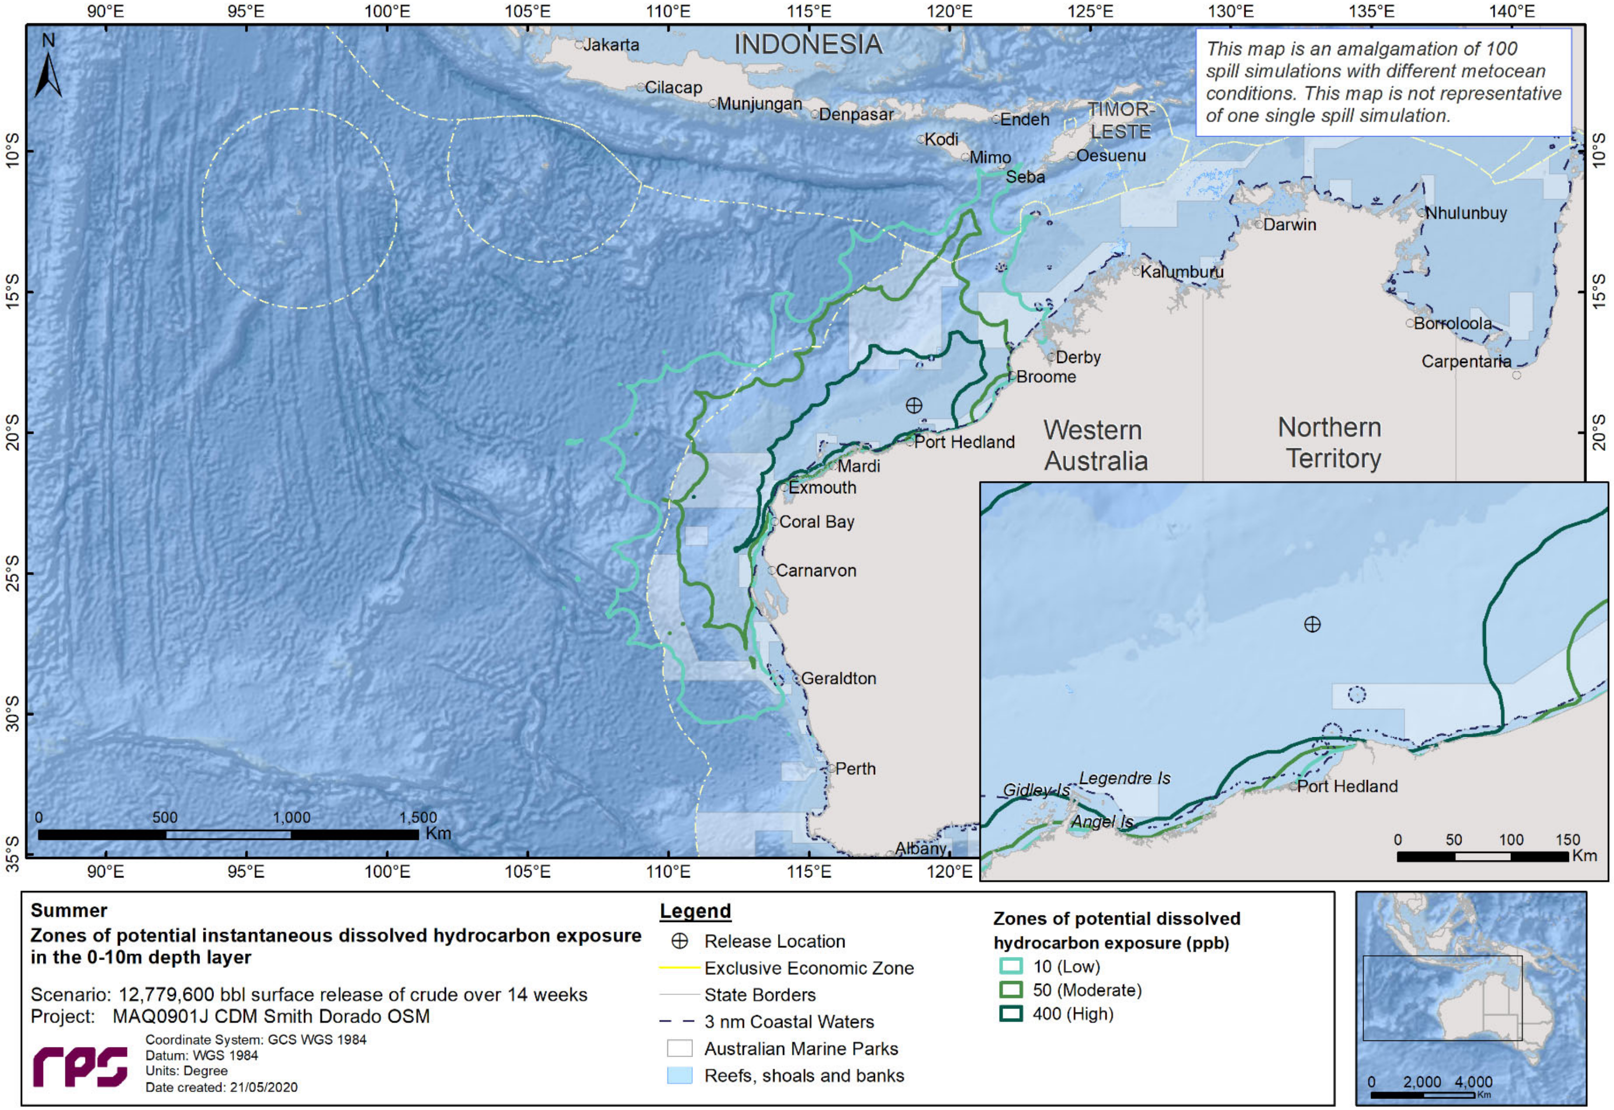

Figure 9.48 Predicted dissolved hydrocarbon exposure zones resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

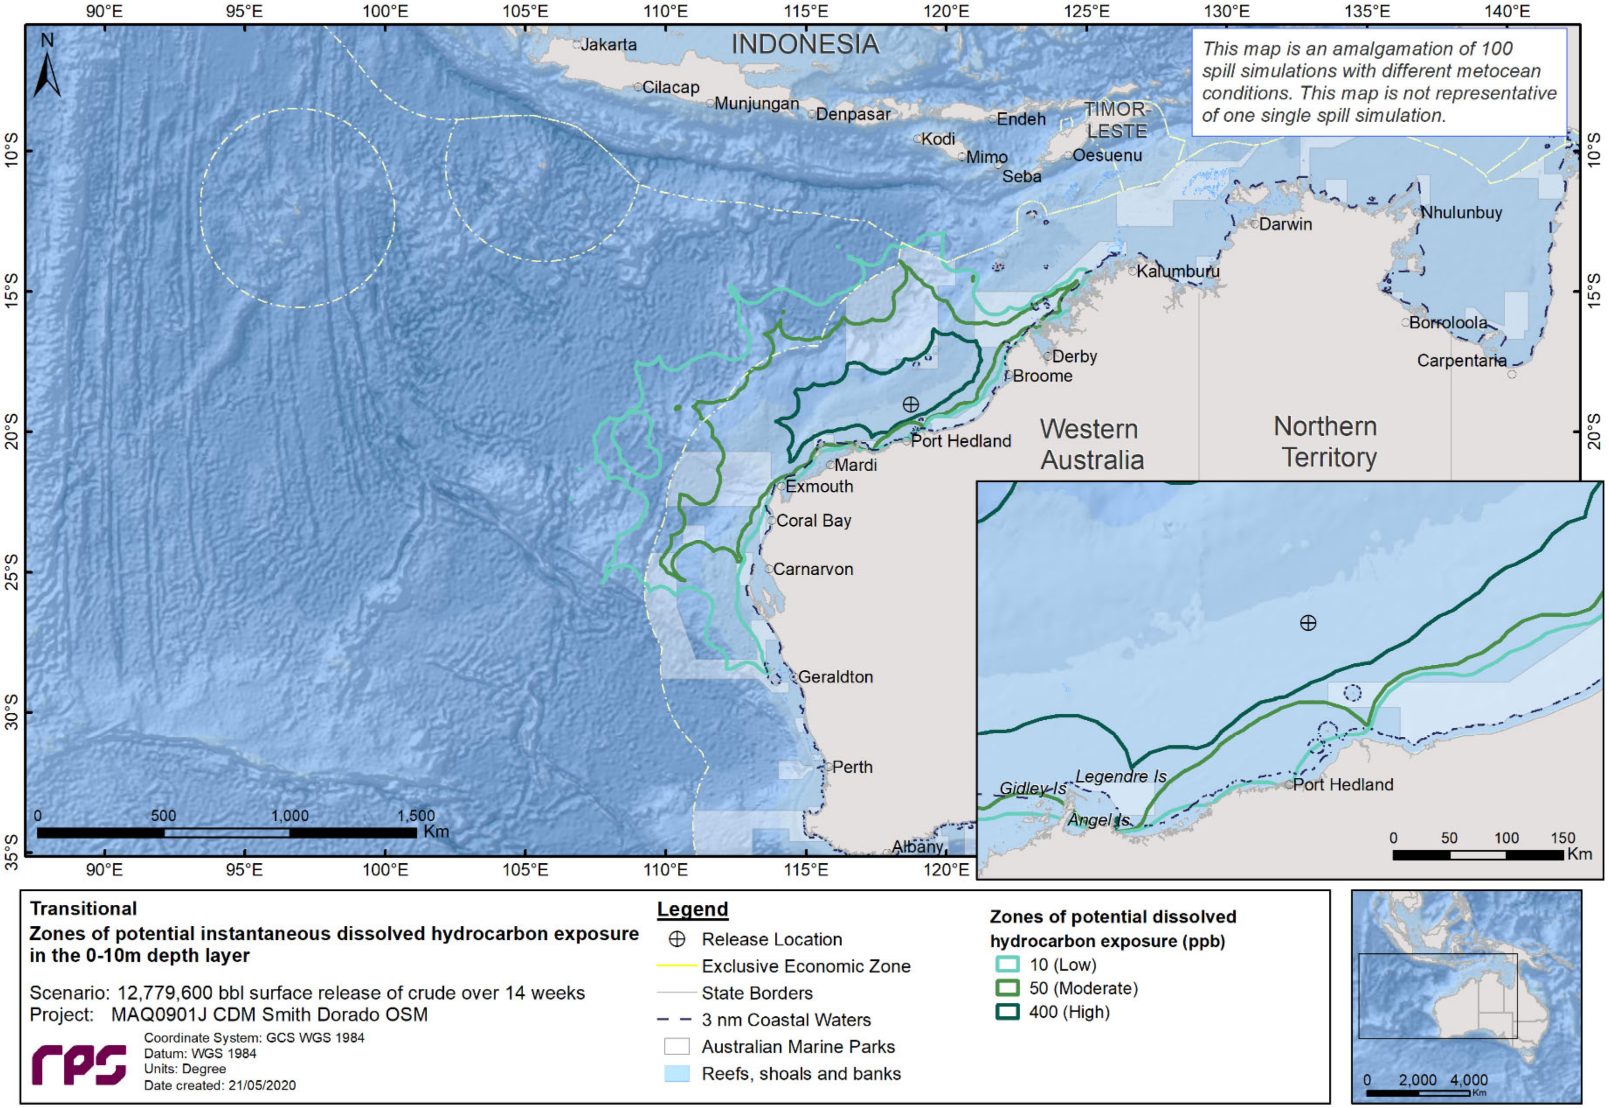

Figure 9.49 Predicted dissolved hydrocarbon exposure zones resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m³) of crude from the WHP. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

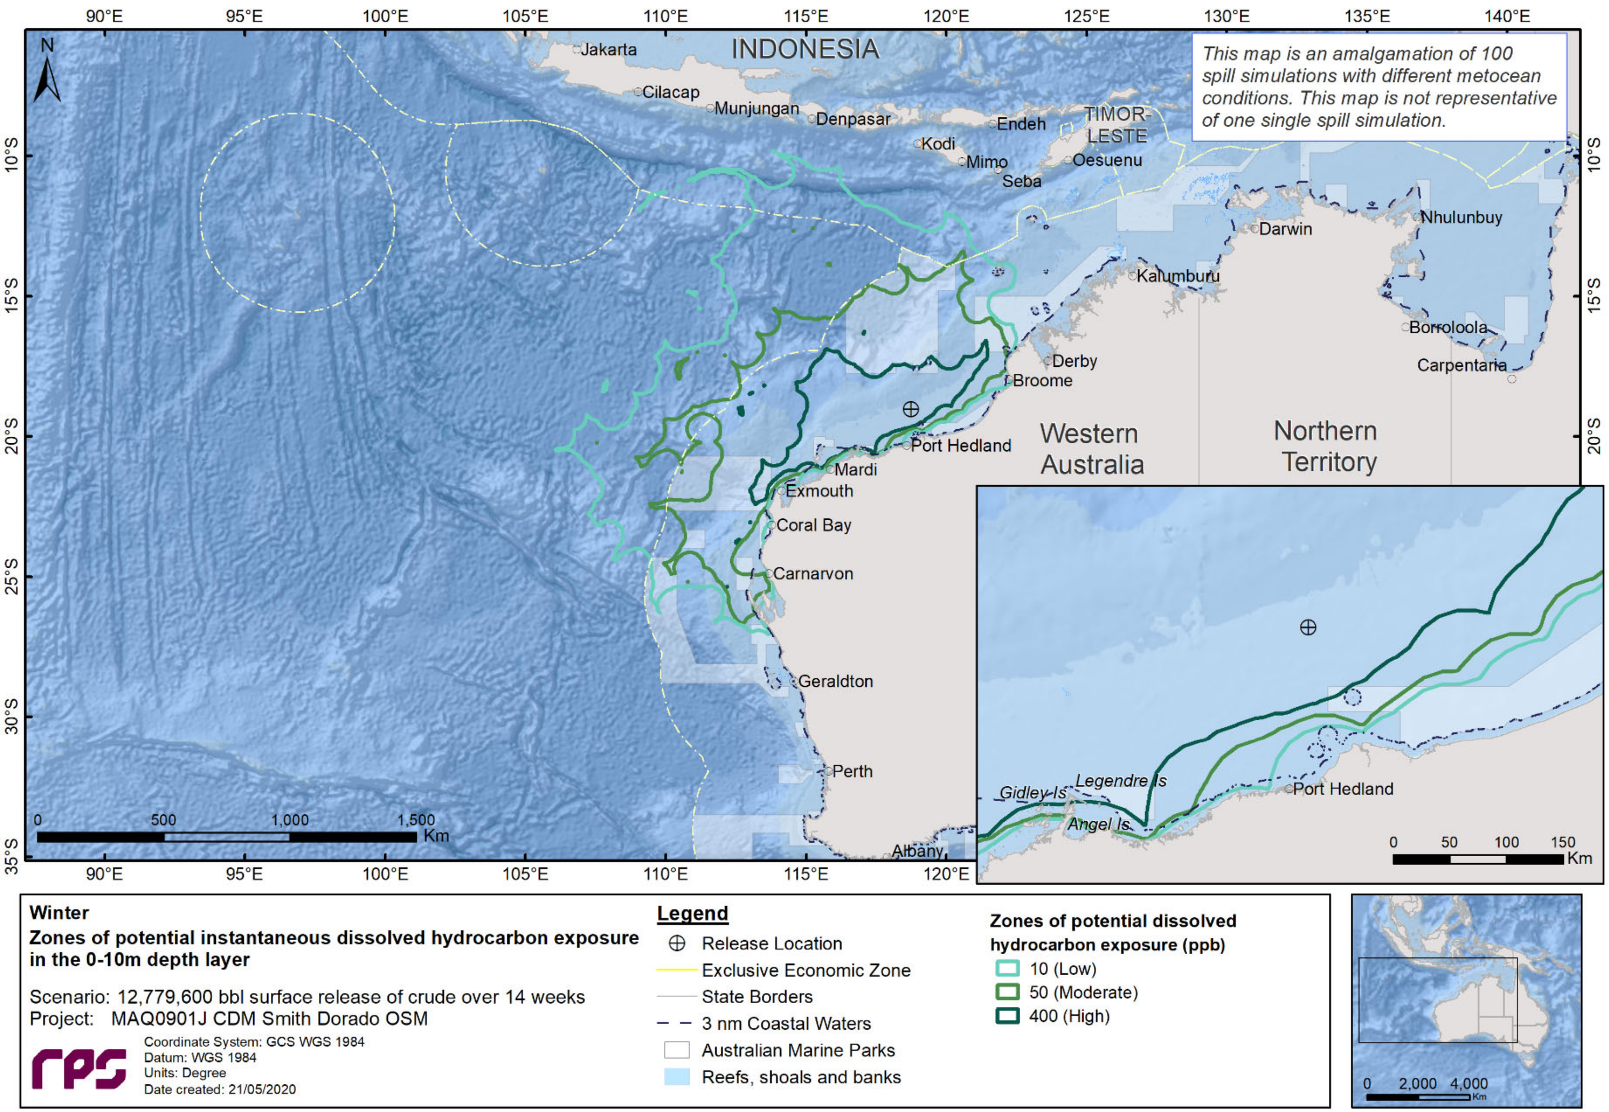

Figure 9.50 Predicted dissolved hydrocarbon exposure zones resulting from a surface blowout over 14 weeks, releasing a total 12,779,600 bbl (2,031,794 m^3) of crude from the WHP. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.3 Scenario 3: Simulation of a 1-hour subsea release of crude from the export pipeline between the FPSO and WHP

This scenario examined a 1,080 m^3 subsea release of crude over 1 hour, tracked for 35 days. A total of 300 simulations were run across three seasons; summer, transitional and winter (i.e. 100 spills per season). These are then combined and presented as exposures zones for each season (cumulative of 100 simulations) for the low, moderate and high thresholds.

Sections 9.3.1 presents overview of the EMBA based on combining the 300 spill simulations and Section 9.3.3 shows the seasonal (or stochastic) analysis. As there was no shoreline accumulation predicted for any spills during this scenario, the deterministic analysis (i.e. a single spill simulation) results presented in Section 9.3.2 are based on the largest area of floating oil (above 50 g/m^2) and the largest area of entrained hydrocarbons.

9.3.1 Overview

Figure 9.51 and Figure 9.52 are maps which encompass the full geographic EMBA derived by overlaying the combined results from all 300 spill simulations at both the low and moderate exposure thresholds, respectively.

Figure 9.53 and Figure 9.54 show the annualised extent of floating oil and in-water (entrained and dissolved) exposure based on the low and moderate exposure thresholds, respectively, derived from combining the results from all 300 spill simulations.

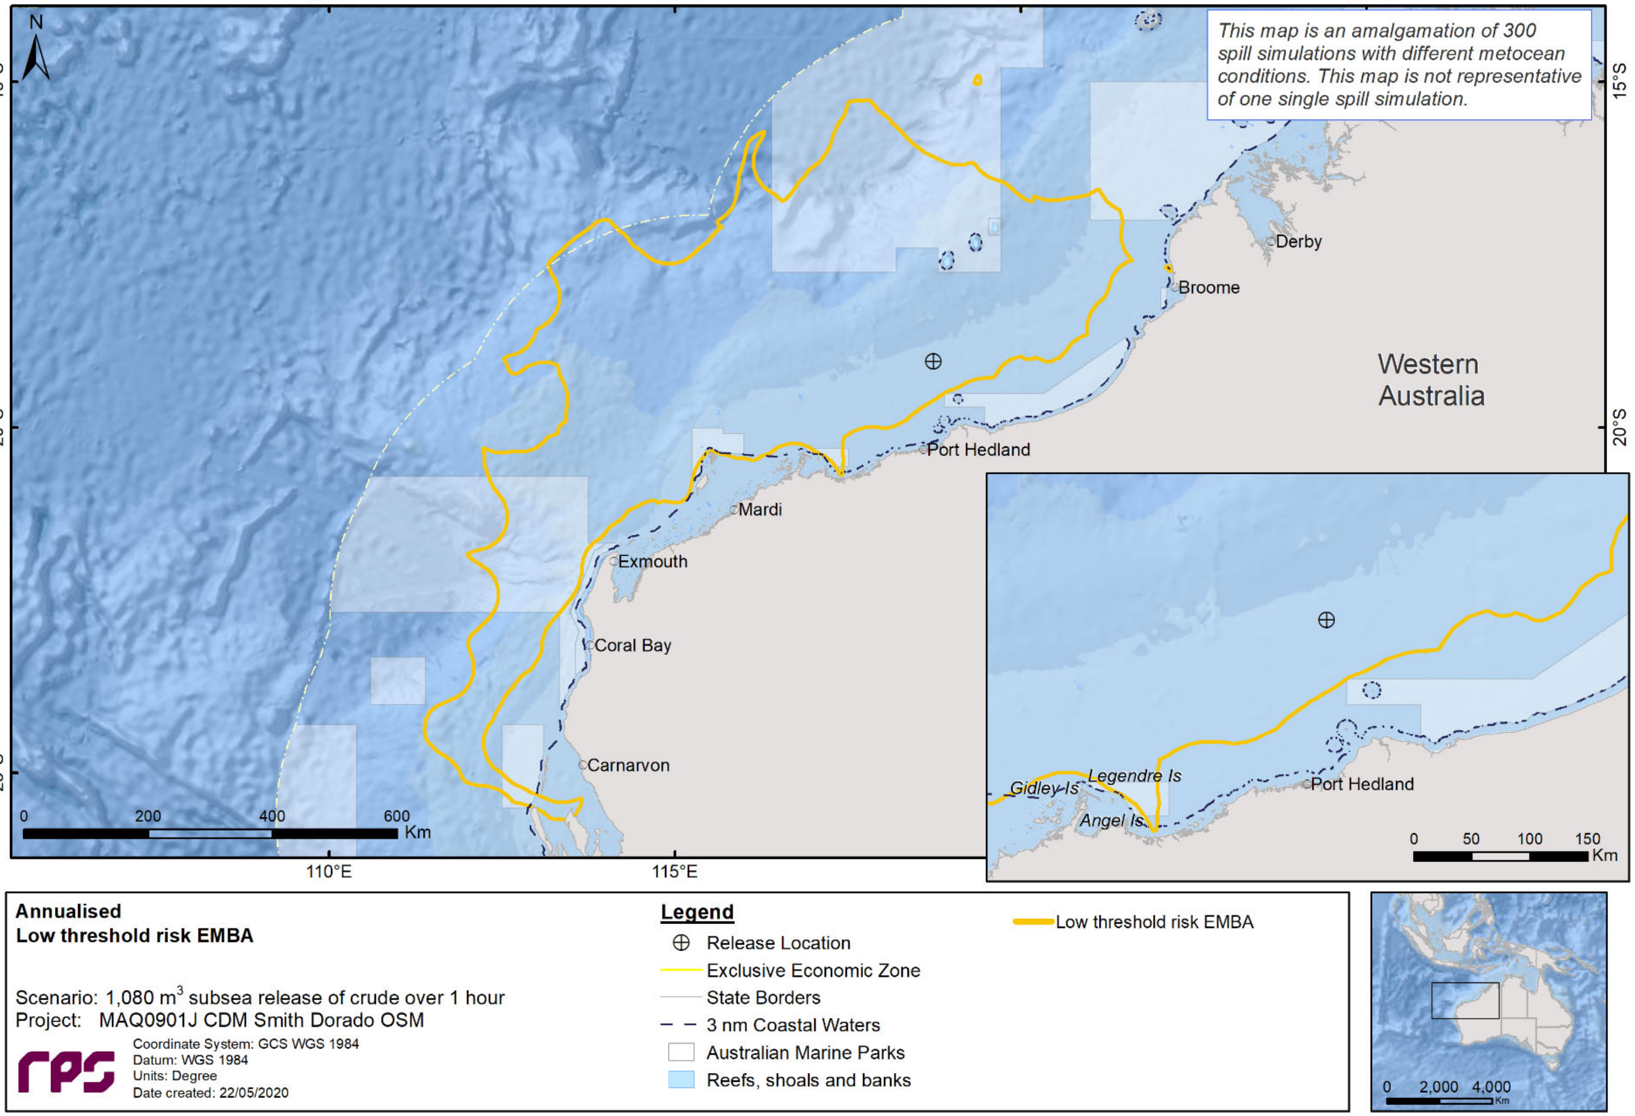

Figure 9.51 Predicted low threshold risk EMBA resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The annualised results were calculated from 300 spill simulations, which were tracked for 35 days.

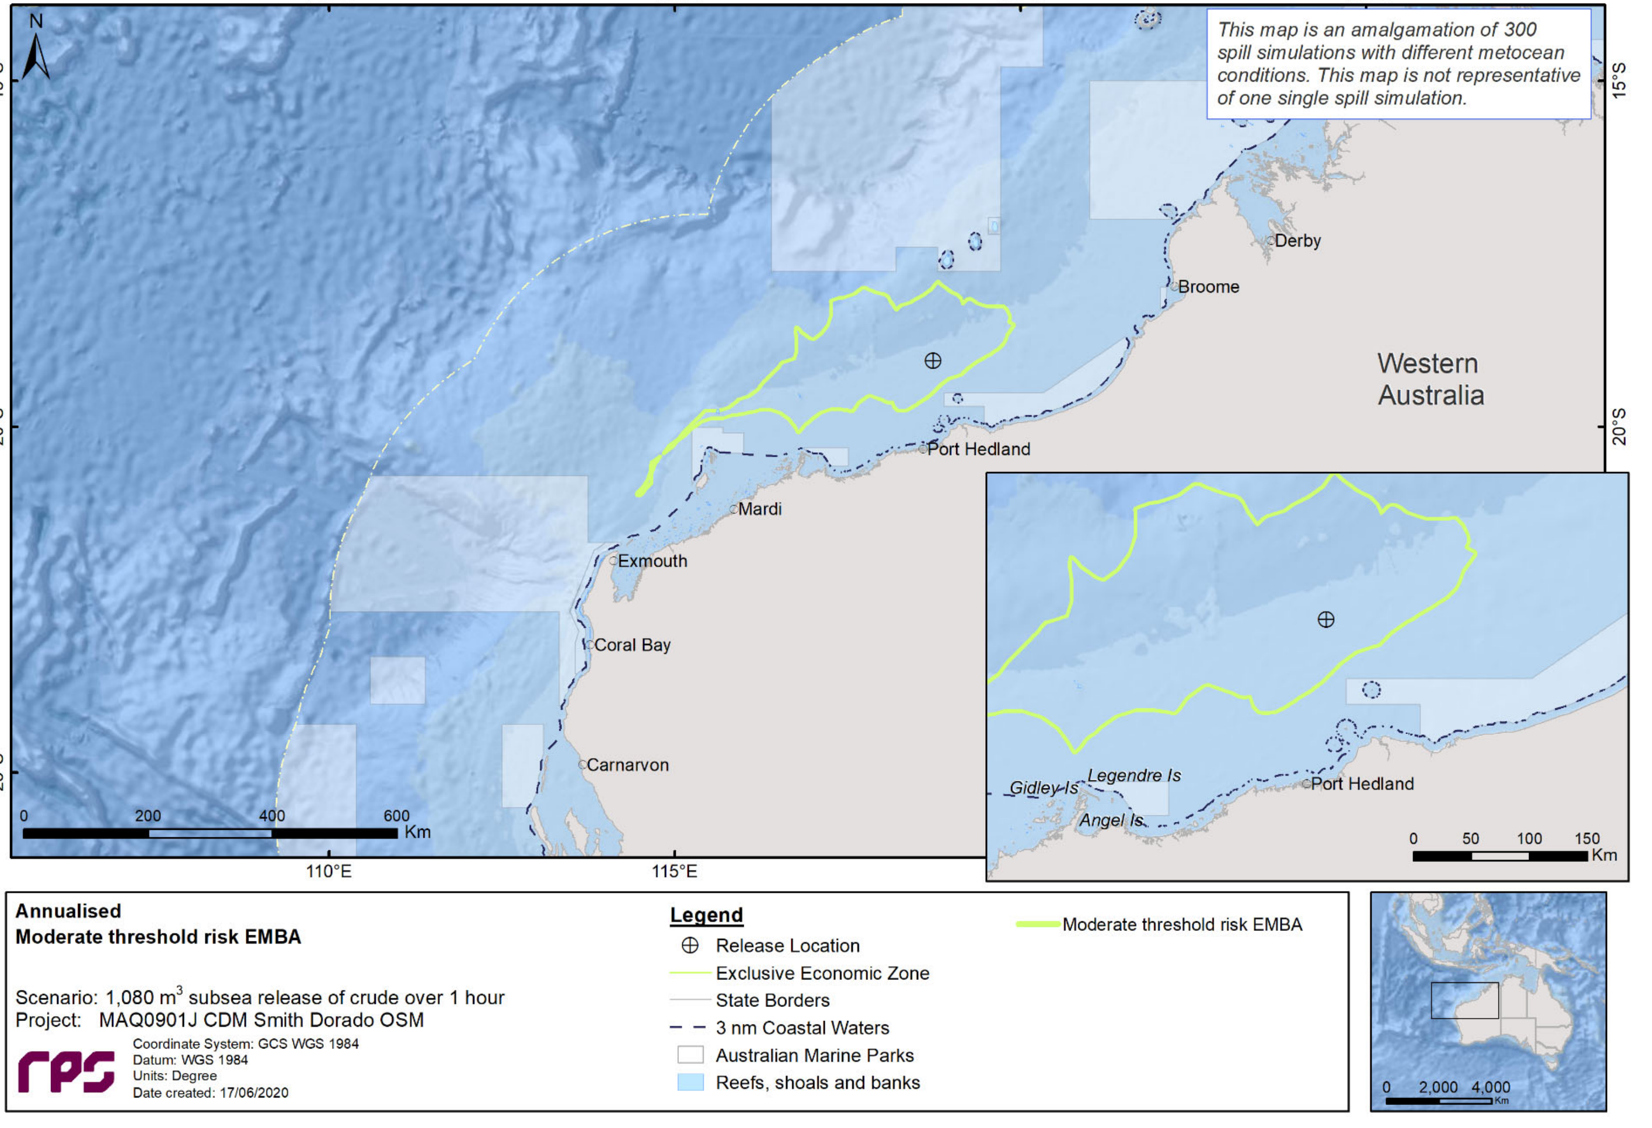

Figure 9.52 Predicted moderate threshold risk EMBA resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The annualised results were calculated from 300 spill simulations, which were tracked for 35 days.

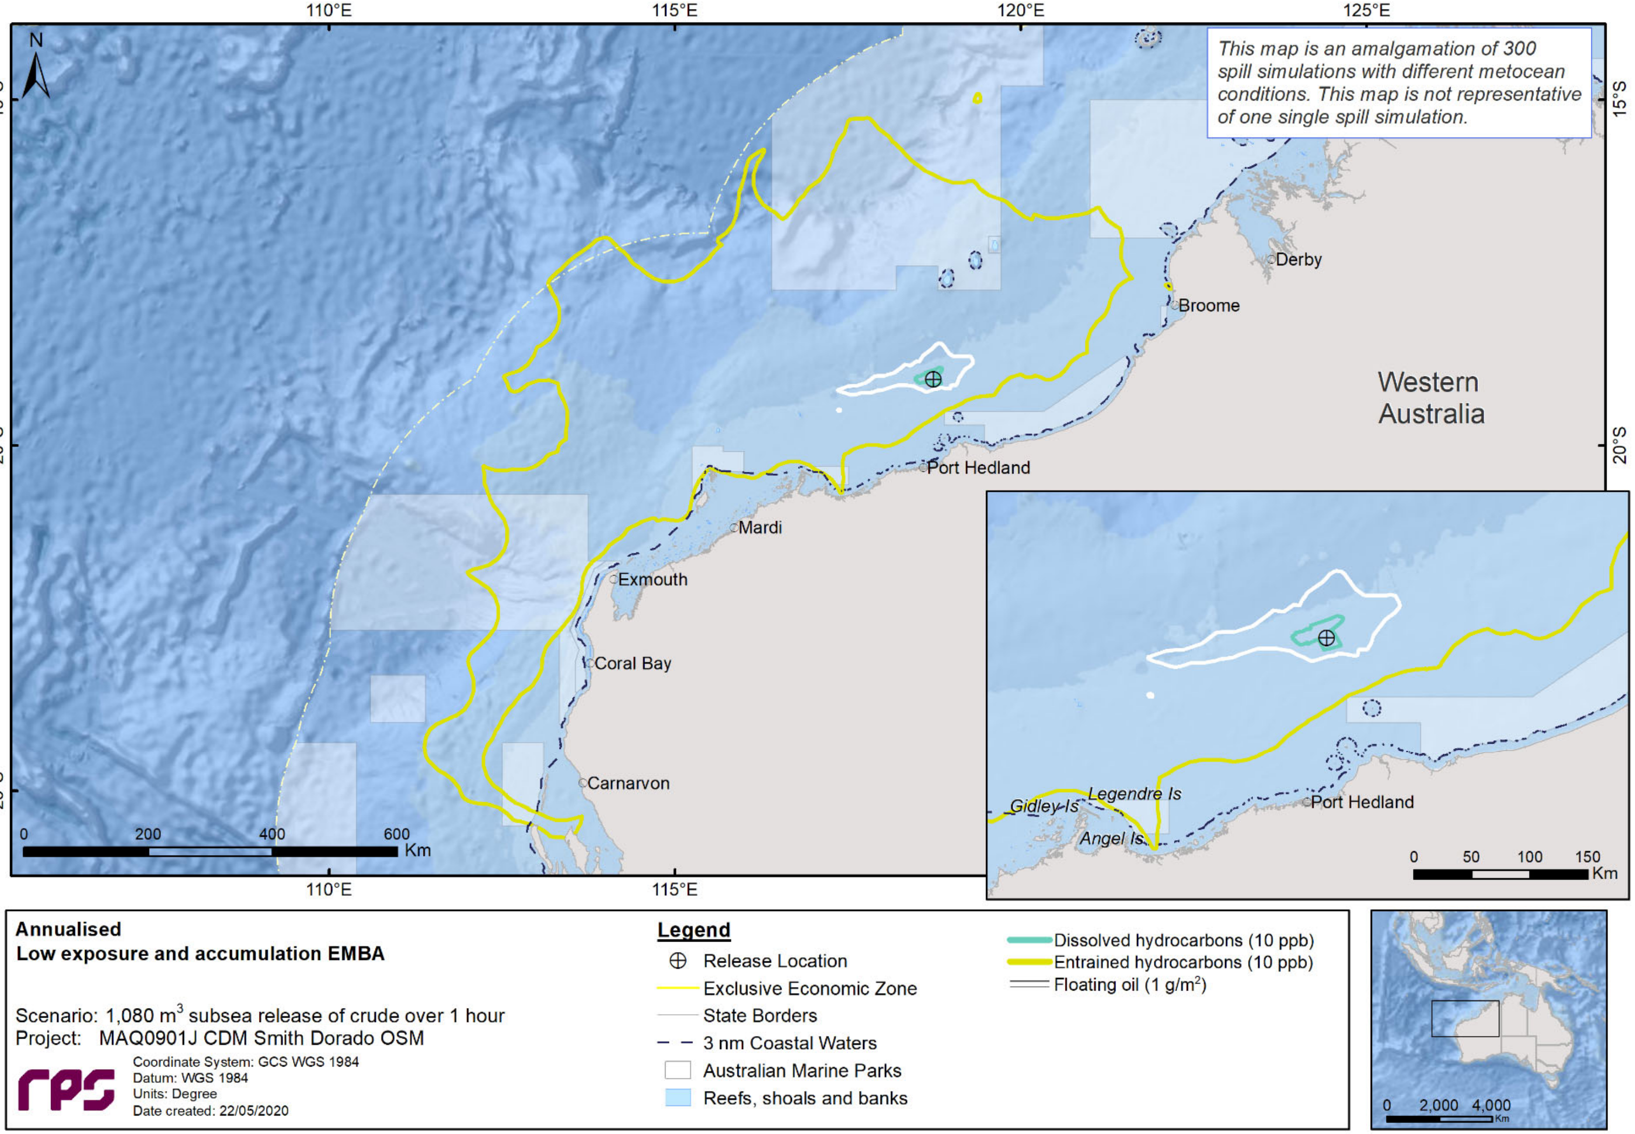

Figure 9.53 Annualised low threshold oil exposure resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The annualised results were calculated from 300 spill simulations, which were tracked for 35 days.

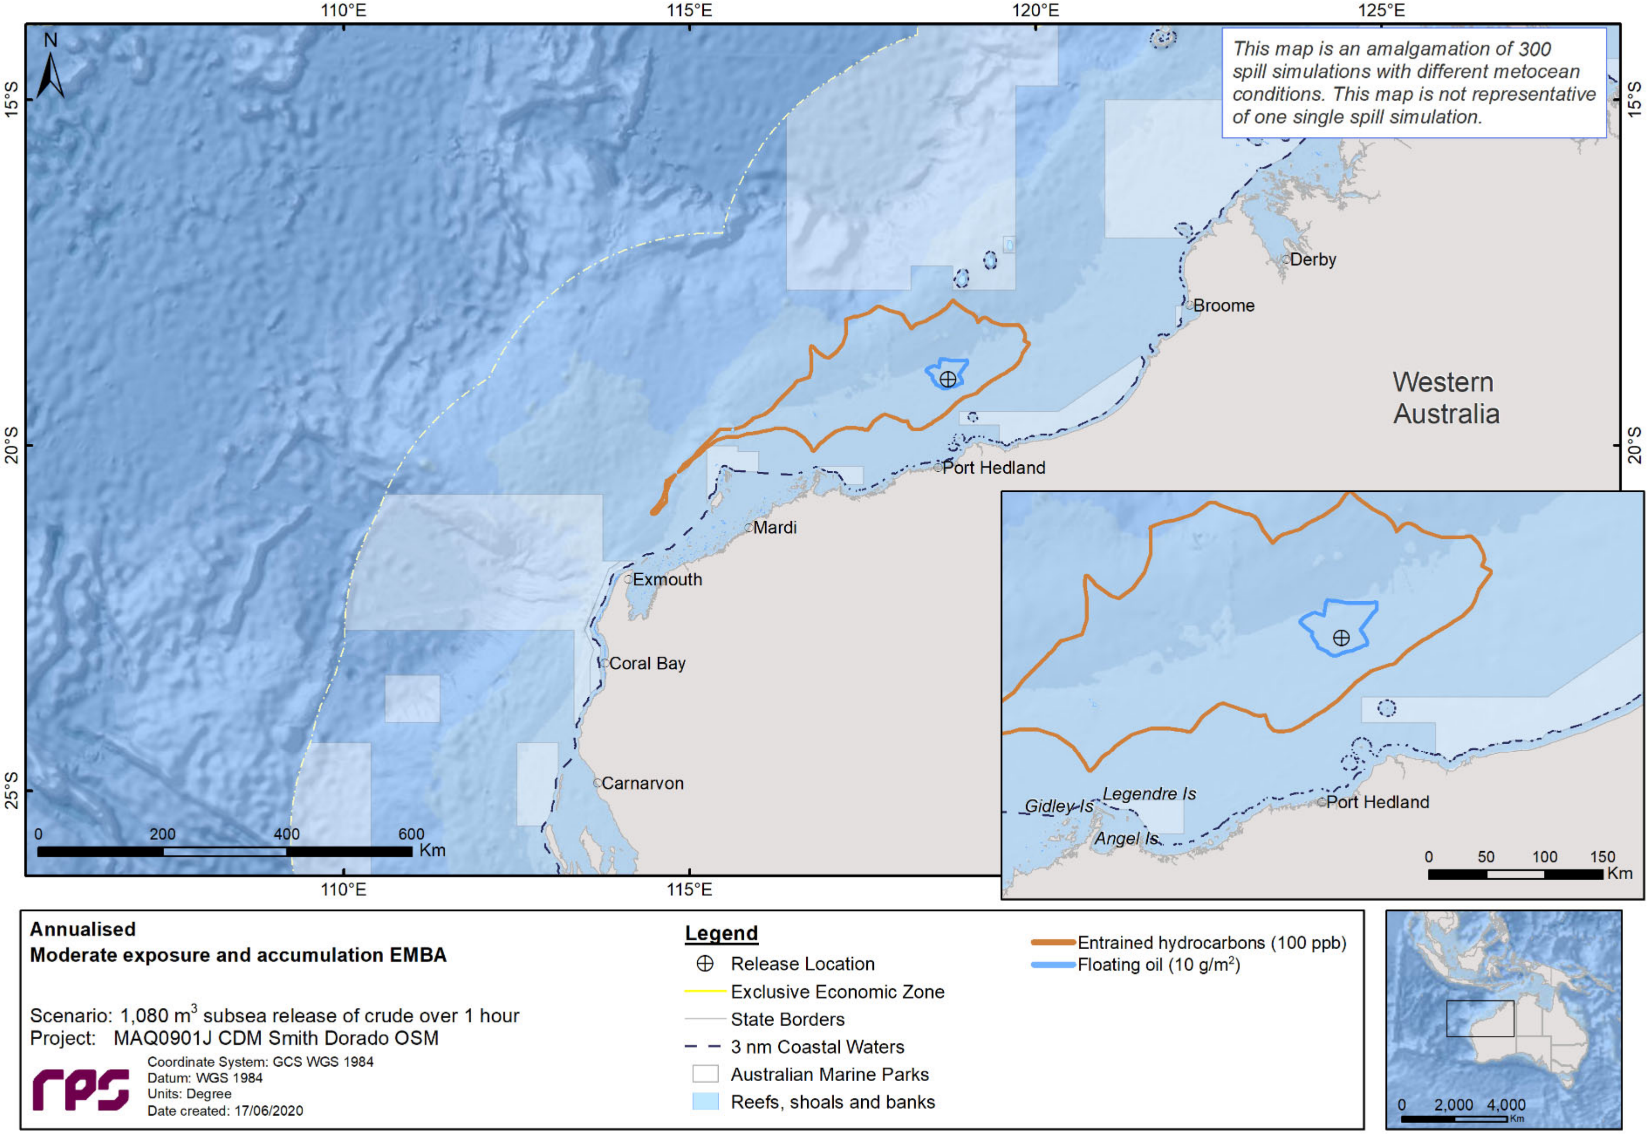

Figure 9.54 Annualised moderate threshold oil exposure resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The annualised results were calculated from 300 spill simulations, which were tracked for 35 days.

9.3.2 Deterministic Analysis

The stochastic modelling results were assessed and the deterministic runs were identified and presented below based on the following criteria;

a. Largest area of floating oil above 50 g/m^2 (actionable floating oil); and

b. Largest area of entrained hydrocarbon exposure

9.3.2.1 Deterministic Case: Largest Area of Floating Oil above 50 g/m^2

The deterministic simulation that resulted in the largest area of floating oil above 50 g/m^2 (high or actionable surface oil threshold) was identified during winter conditions as run number 18, which commenced at 2 pm on the 18th of July 2016.

Exposure from floating oil (swept area) over the entire 35 day simulation is presented in Figure 9.55. Floating oil exposure was predicted north from the release location up to a maximum distance of approximately 37 km at the low (1-10 g/m^2) threshold. Floating oil at the moderate (10-50 g/m^2) and high (≥50 g/m^2) thresholds were predicted to extend approximately 32 km and 15 km north of the release location, respectively.

Figure 9.56 displays the time series of the area of visible oil (≥1 g/m^2) and actionable floating oil (≥50 g/m^2) exposure on the sea surface over the 35-day simulation. The maximum area of coverage of visible oil on the sea surface was predicted to occur 2 days after the spill started and covered approximately 23 km^2.

Figure 9.57 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 837 m^3 (78%) spilled oil was lost to the atmosphere through evaporation. Approximately 129 m^3 (12%) of the crude was predicted to have decayed, while approximately 113 m^3 (10%) was predicted to remain within the water column.

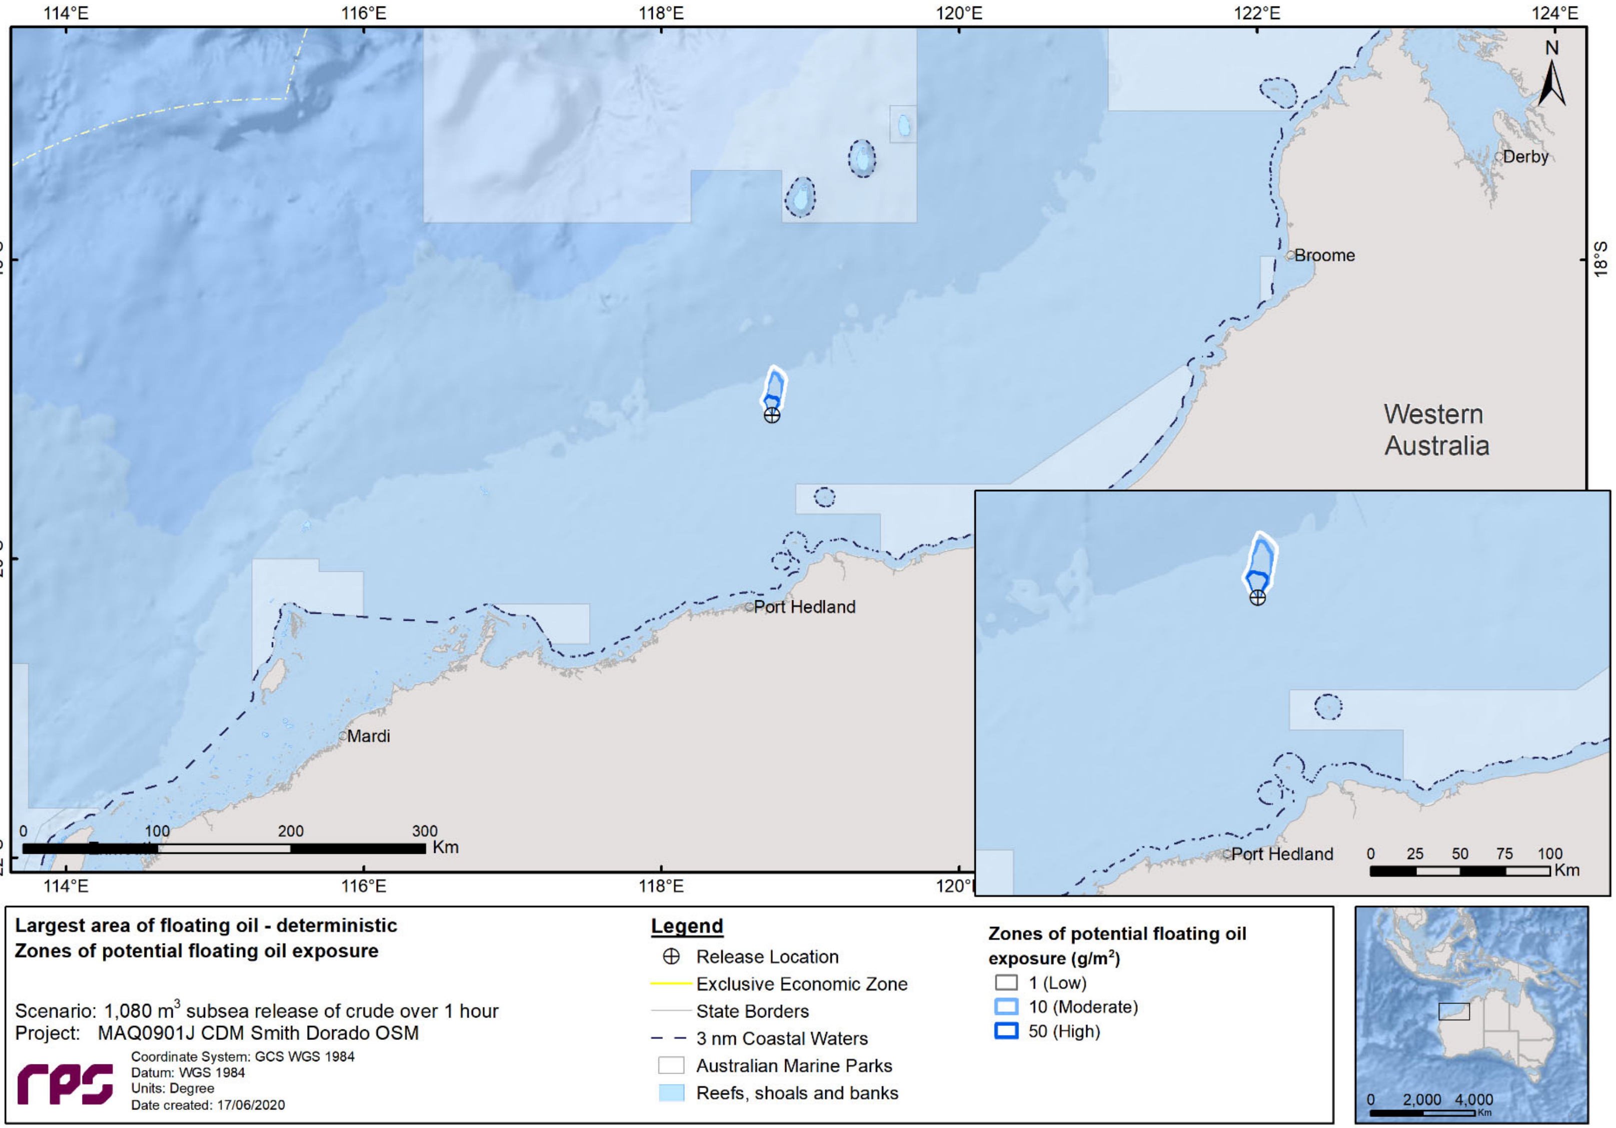

Figure 9.55 Exposure from floating oil (over the 35 day simulation) for the simulation with the largest area of floating oil above 50 g/m^2. Results are based on a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline, starting 2 pm on the 18th of July 2016.

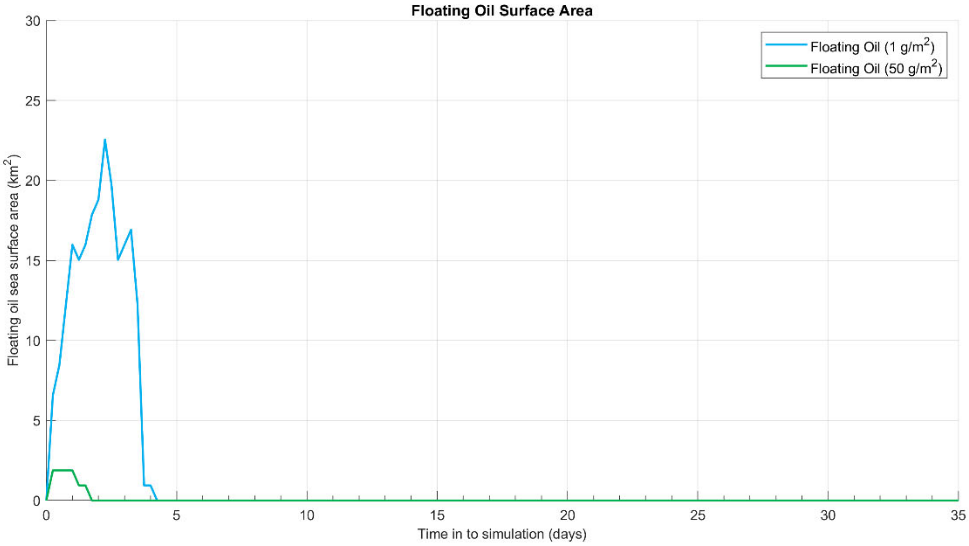

Figure 9.56 Time series of the area of visible (≥1 g/m²) and actionable floating oil (≥50 g/m²) on the sea surface for the simulation with the largest area of floating oil above 50 g/m². Results are based on a subsea release over 1 hour, releasing a total of 1,080 m³ of crude from the export pipeline, tracked for 35 days, 2 pm on the 18th of July 2016.

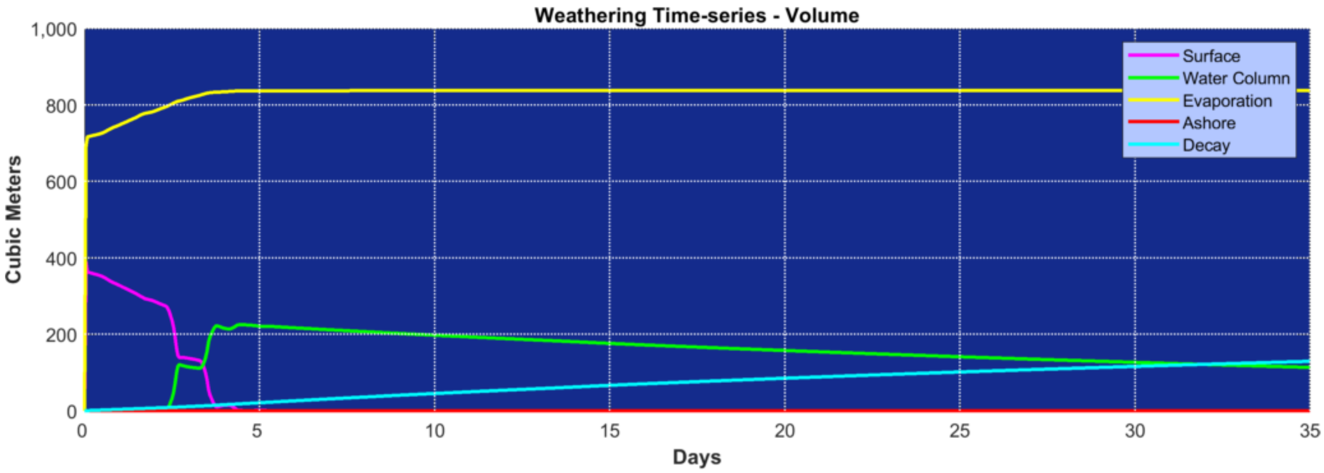

Figure 9.57 Predicted weathering and fates graph for the single spill simulation with the largest area of floating oil above 50 g/m². Results are based on a subsea release over 1 hour, releasing a total of 1,080 m³ of crude from the export pipeline, tracked for 35 days, 2 pm on the 18th of July 2016.

9.3.2.2 Deterministic Case: Largest Area of Entrained Hydrocarbons

The deterministic simulation that resulted in the largest area of entrained hydrocarbons was identified during transitional conditions as run number 18, which commenced at 9 pm on the 15th of September 2018.

Exposure from floating oil (swept area) over the entire 35 day simulation are presented in Figure 9.58. Floating oil exposure was predicted to remain within approximately 18 km west of the release location.

Figure 9.59 presents instantaneous entrained hydrocarbon exposure zones in the 0-10 m depth layer for the entire simulation. Entrained hydrocarbons at the low threshold (10-100 ppb) were predicted to extend a maximum distance of approximately 11,019 km southwest from the release location and approximately 524 km southwest at the high threshold.

No dissolved hydrocarbon exposure above the low (10-50 ppb) threshold was predicted for this simulation.

Figure 9.60 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 734 m^3 (68%) spilled oil was lost to the atmosphere through evaporation. Approximately 192 m^3 (18%) of the crude was predicted to have decayed, while approximately 153 m^3 (14%) was predicted to remain within the water column.

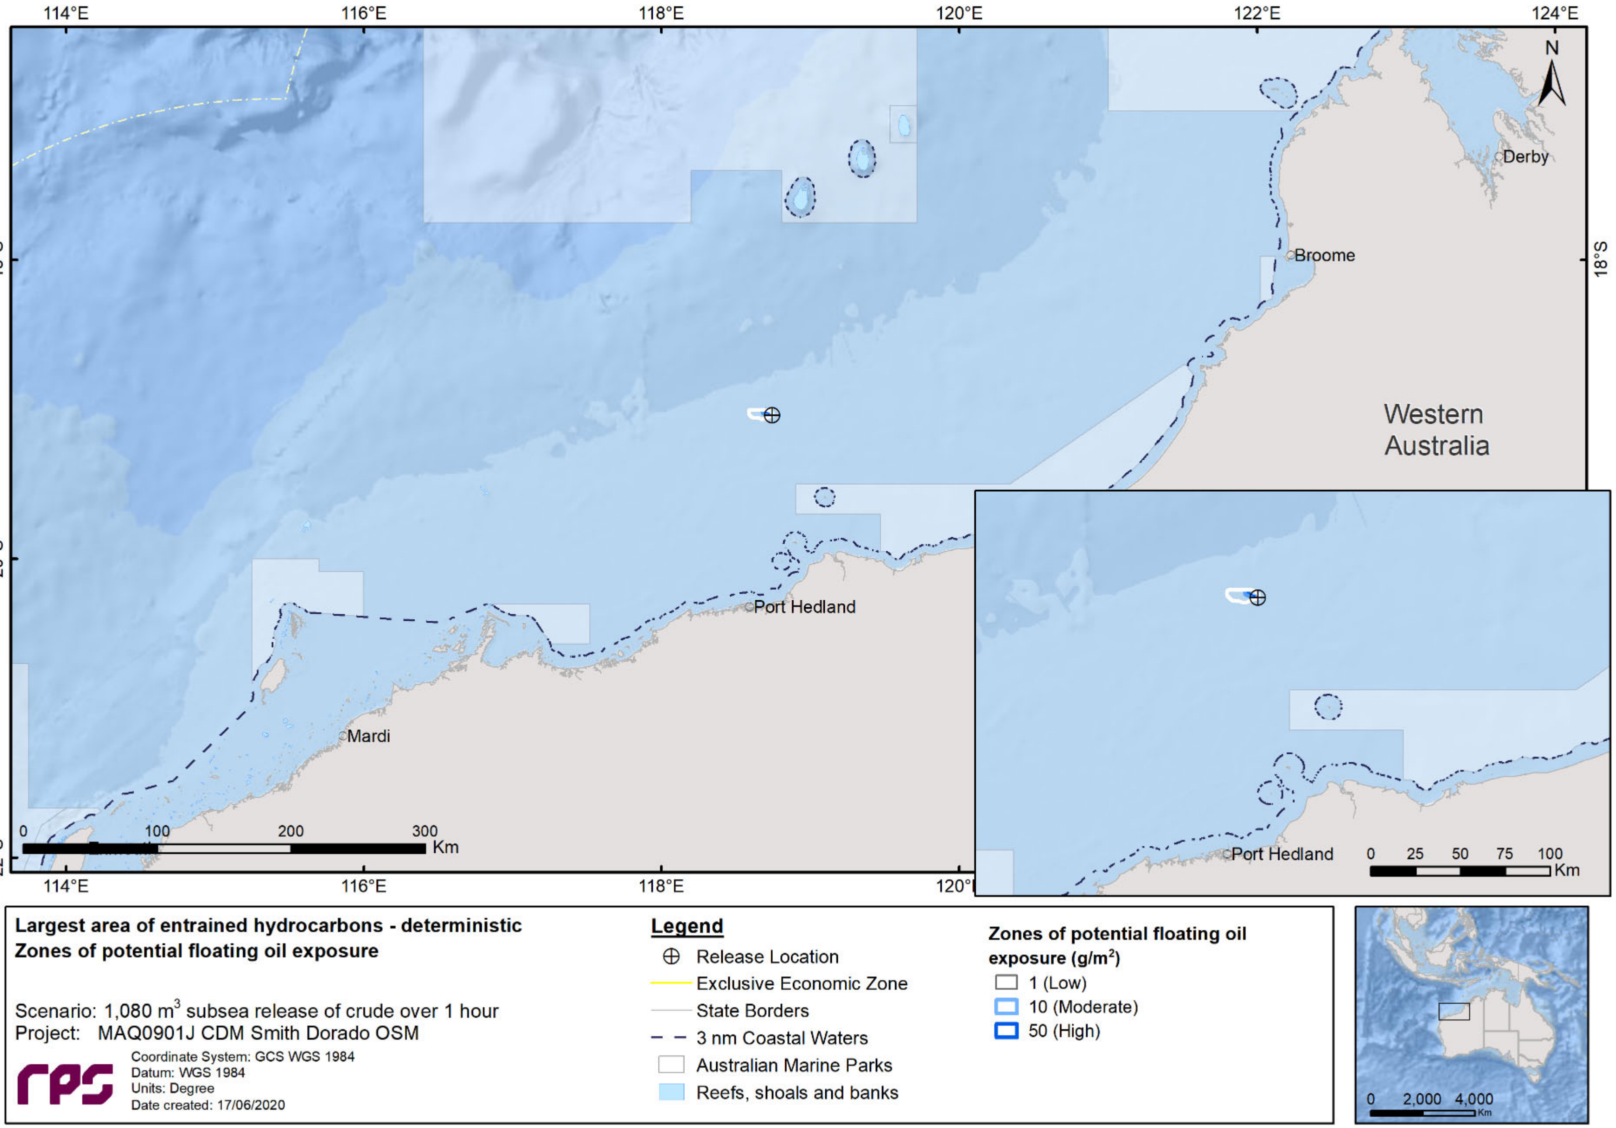

Figure 9.58 Exposure from floating oil (over the 35 day simulation) for the simulation with the largest area of entrained hydrocarbons. Results are based on a subsea release over 1 hour, releasing a total of 1,080 m³ of crude from the export pipeline, starting 9 pm on the 15th of September 2018.

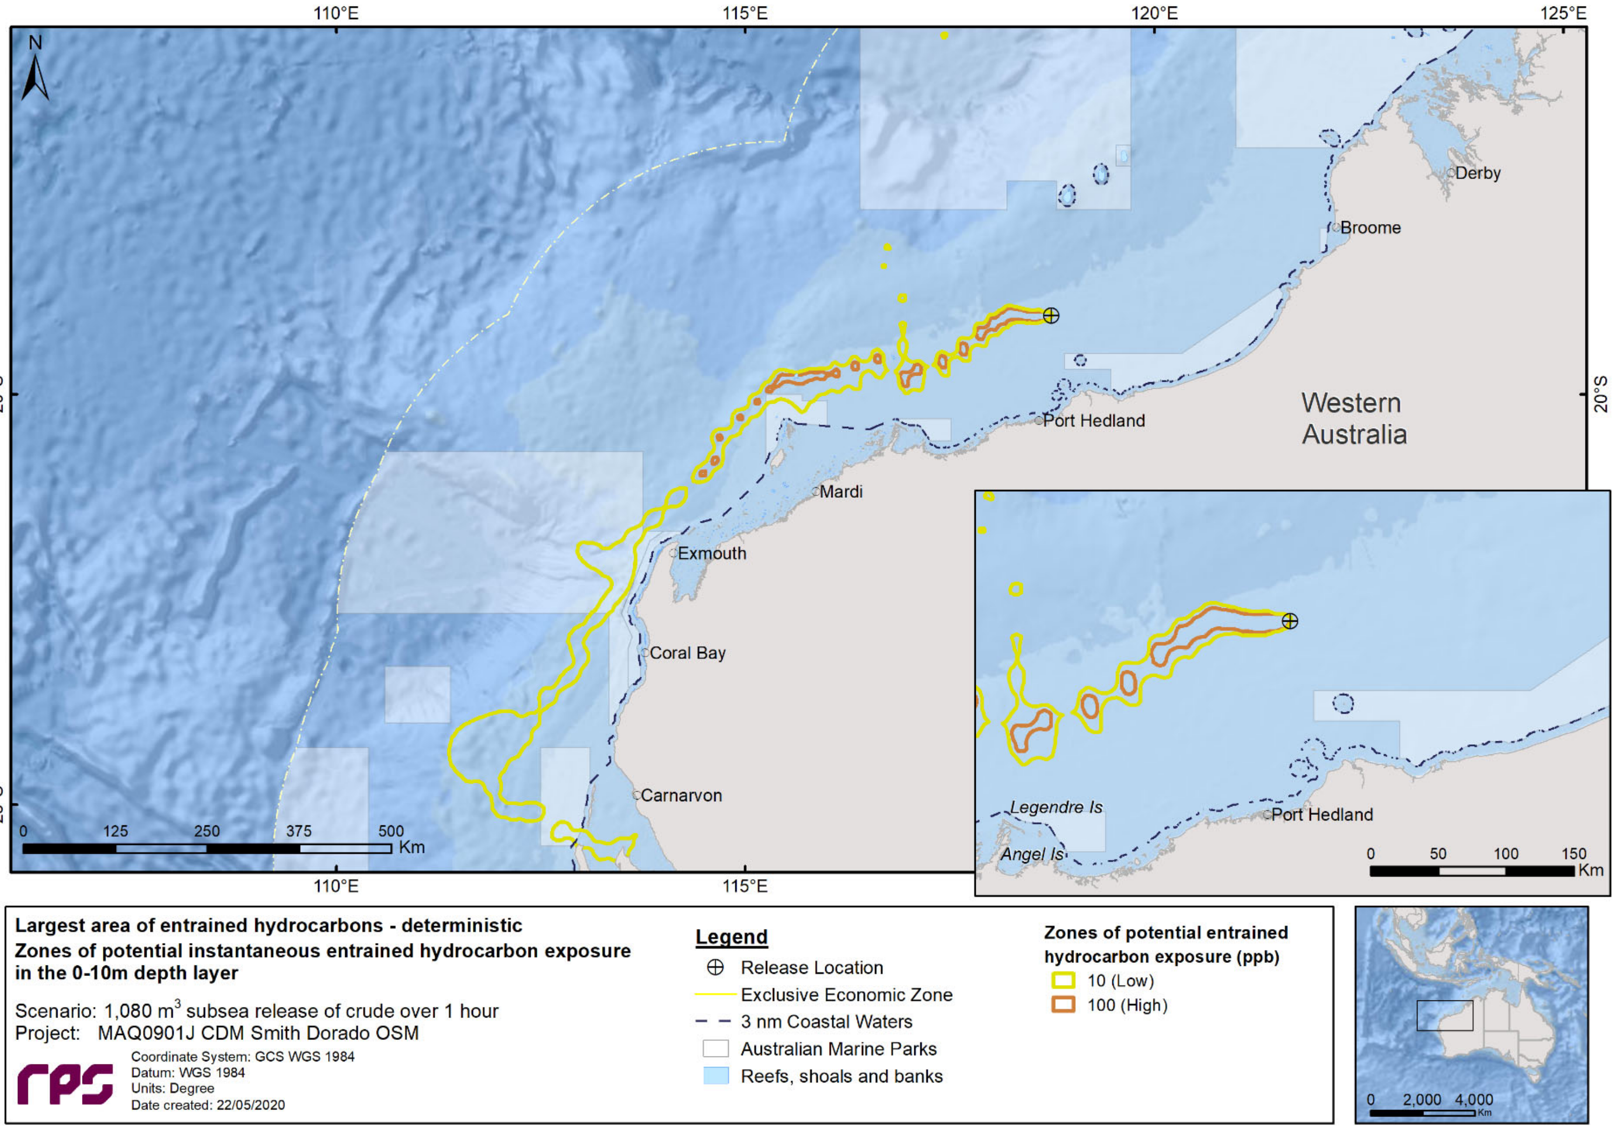

Figure 9.59 Predicted entrained hydrocarbon exposure zones in the 0-10 m depth layer for the simulation with the largest area of entrained hydrocarbons. Results are based on a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline, tracked for 35 days, 9 pm on the 15th of September 2018.

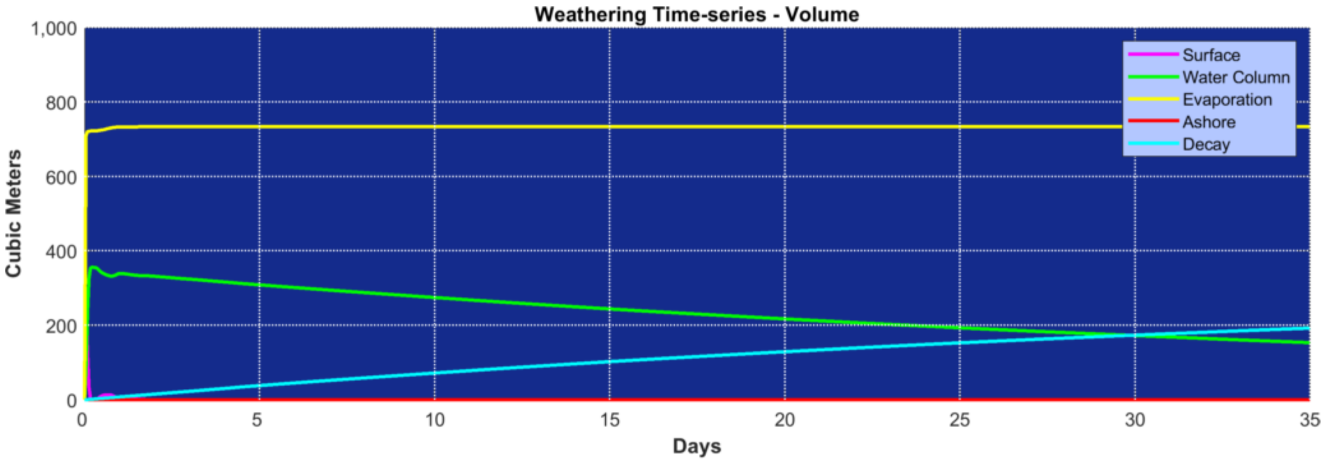

Figure 9.60 Predicted weathering and fates graph for the single spill simulation with the largest area of entrained hydrocarbons. Results are based on a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline, tracked for 35 days, 9 pm on the 15th of September 2018.

9.3.3 Seasonal analysis

9.3.3.1 Floating Oil Exposure

Table 9.27 summarises the maximum distances from the release location to floating oil exposure zones for each season. The maximum distance from the release location to the low (1–10 g/m^2), moderate (10–50 g/m^2) and high (≥ 50 g/m^2) exposure thresholds was 153.1 km west-southwest (transitional), 40.5 km northeast (winter) and 34.6 km west-northwest (transitional), respectively.

Images of floating oil exposure zones are depicted in Figure 9.61, Figure 9.62 and Figure 9.63 for the combined 100 spills commencing during summer, transitional and winter conditions, respectively. There was no floating oil exposure to any of the receptors assessed.

Table 9.27 Maximum distance and direction from the release location to floating oil exposure thresholds. Results are based on a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The results were calculated from 100 spill simulations per season.

Season	Distance and direction	Exposure from floating oil		
		Low (1-10 g/m^2)	Moderate (10-50 g/m^2)	High (≥50 g/m^2)
Summer	Max. distance from release site (km)	146	25.3	19.8
	Max distance from release site (km) (99th percentile)	128.6	23.1	17.7
	Direction	West	Northwest	West-Northwest
Transitional	Max. distance from release site (km)	153.1	35.9	34.6
	Max distance from release site (km) (99th percentile)	63.3	20.5	15.1
	Direction	West-Southwest	West-Northwest	West-Northwest
Winter	Max. distance from release site (km)	57.4	40.5	21.1
	Max distance from release site (km) (99th percentile)	51.9	37.1	18.9
	Direction	North	Northeast	North-Northeast

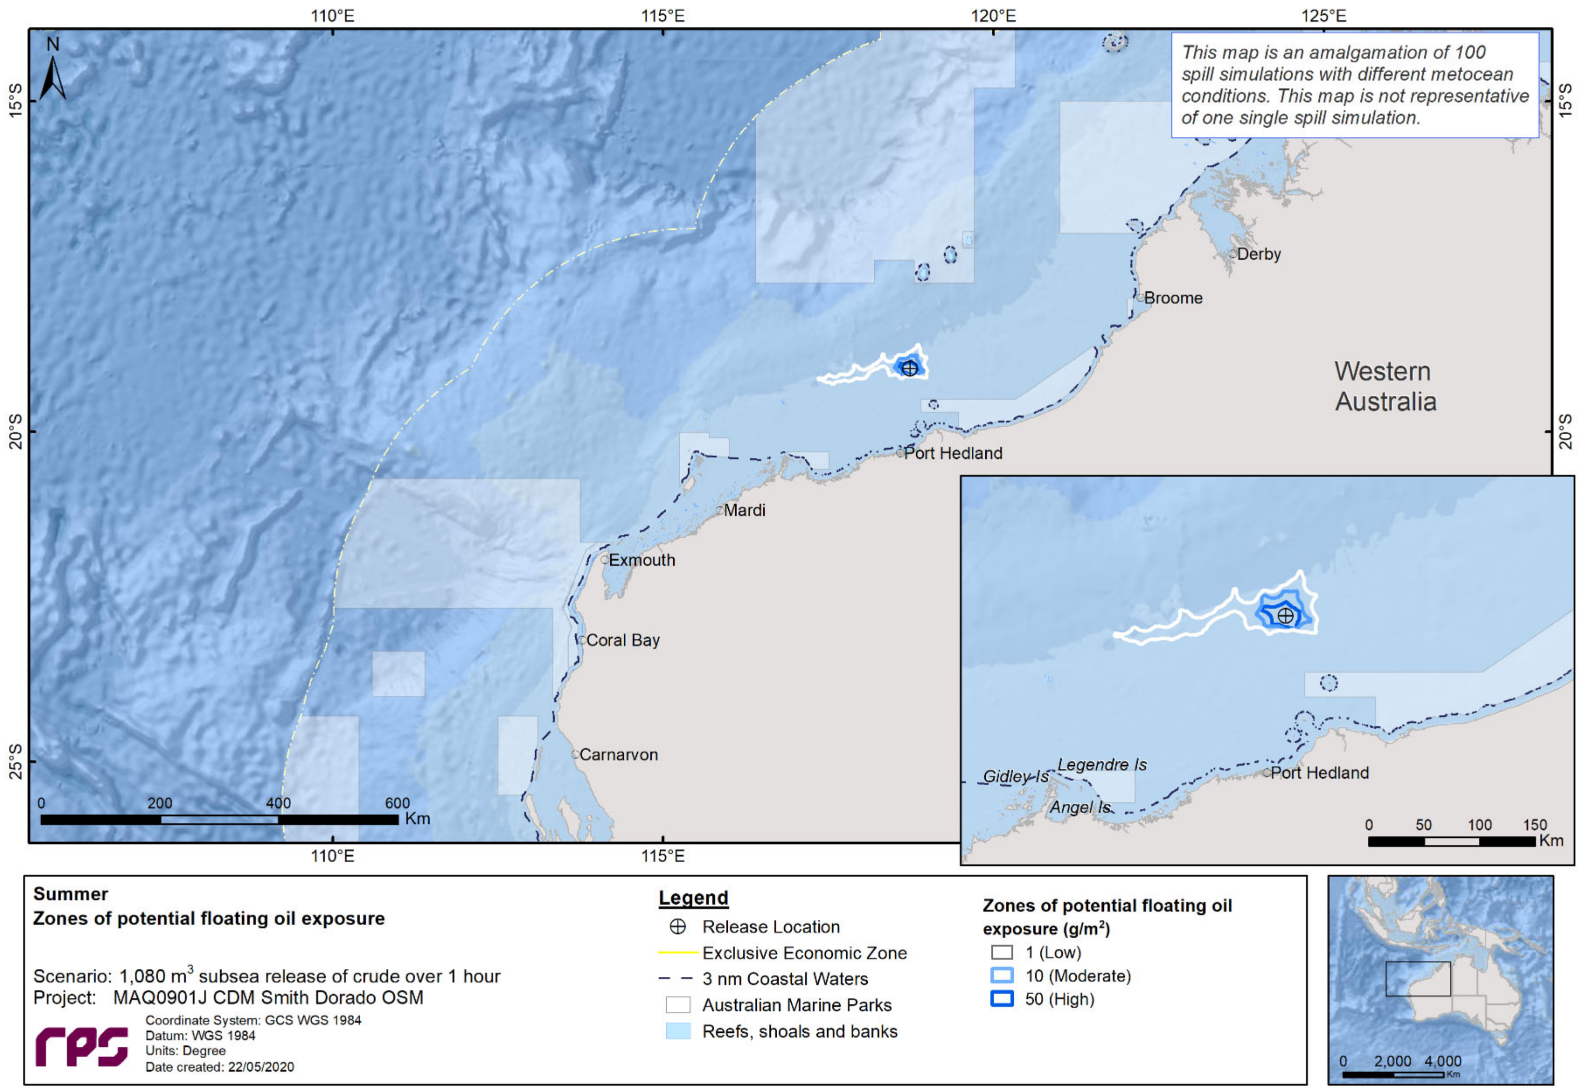

Figure 9.61 Predicted zones of potential floating oil resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

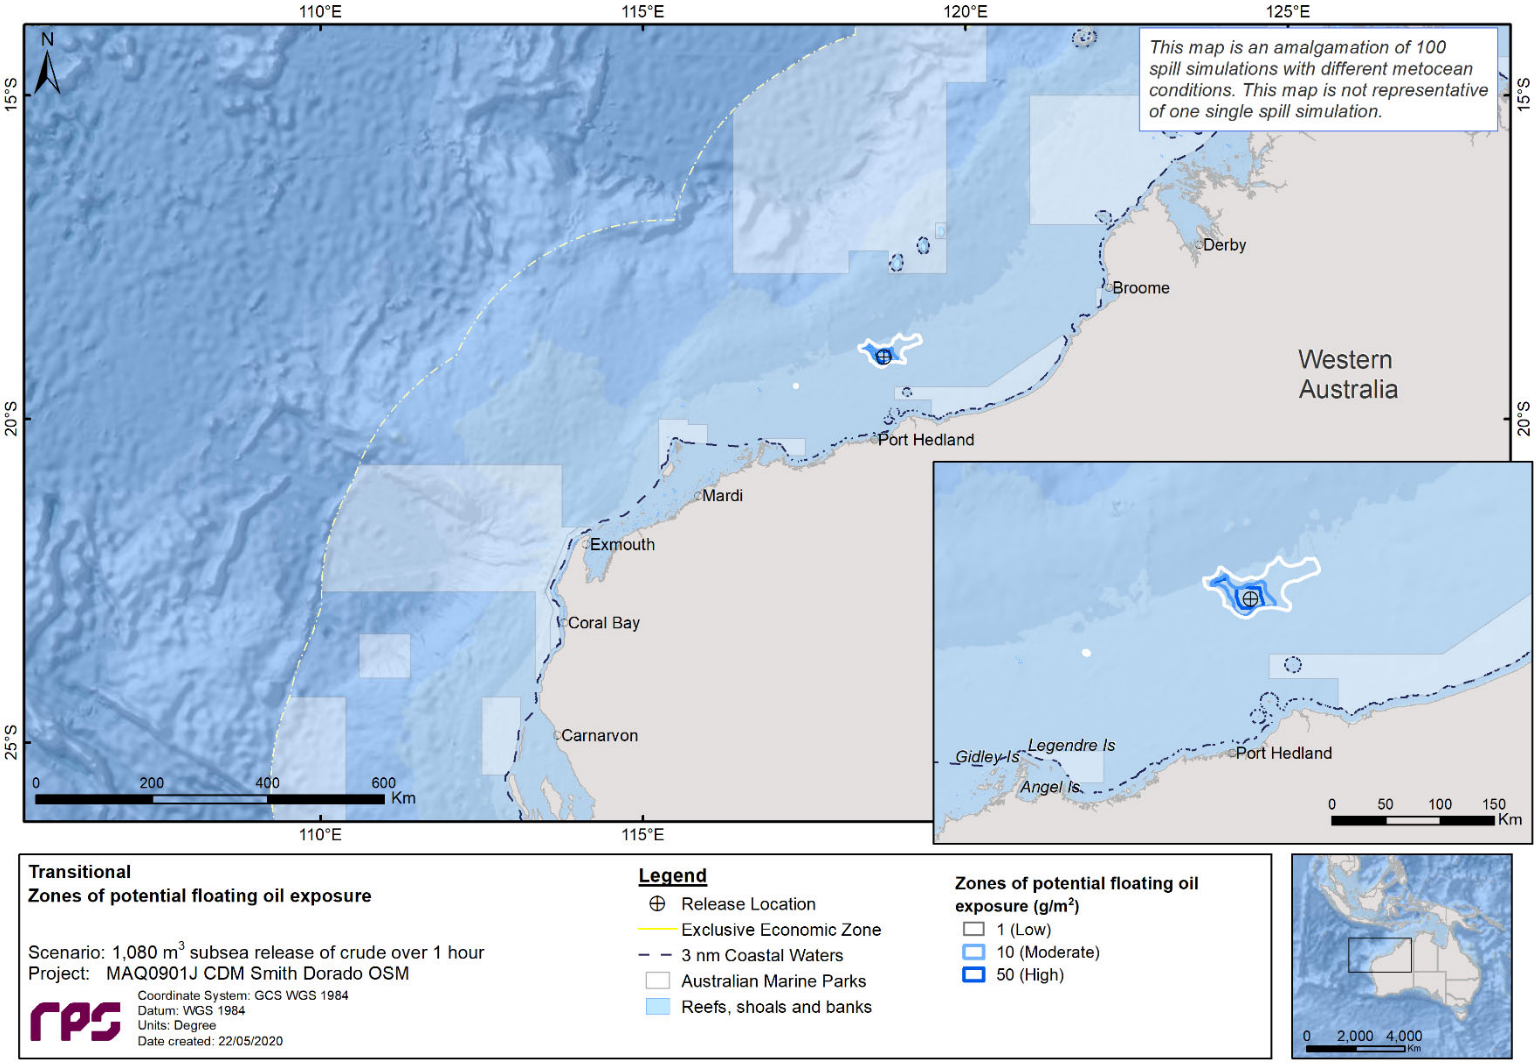

Figure 9.62 Predicted zones of potential floating oil resulting from a subsea release over 1 hour, releasing a total of 1,080 m³ of crude from the export pipeline. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

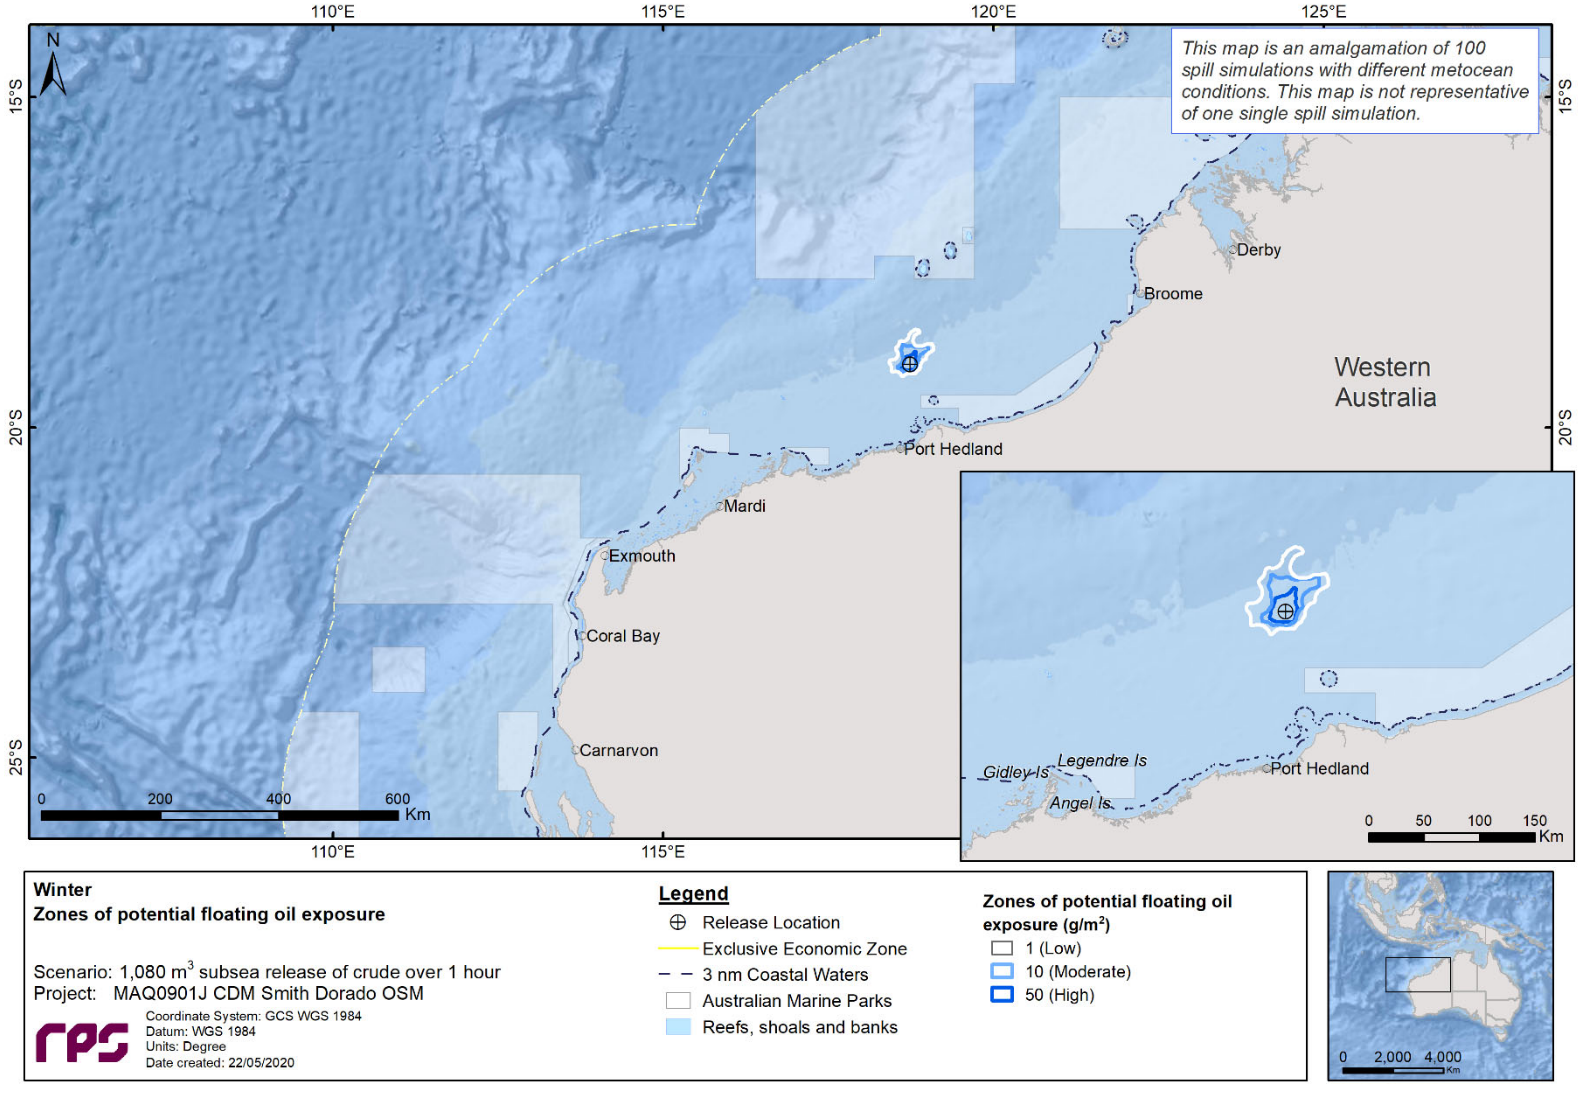

Figure 9.63 Predicted floating oil exposure zones resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.3.3.2 Shoreline Accumulation

There was no shoreline accumulation predicted for any spills during this scenario at, or above, the low threshold (≥10 g/m^2).

9.3.3.3 Entrained Hydrocarbons

Images of entrained hydrocarbon exposure in the 0-10 m depth layer are depicted in Figure 9.64, Figure 9.65 and Figure 9.66 for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively. The results indicated that exposure at the low threshold was predicted to occur up to a maximum distance of 972 km (southwest) from the spill site during transitional conditions. This distance reduced to 497 km (west-southwest) as the threshold increased to moderate in transitional conditions. The maximum distances for summer and winter conditions at the low threshold were 586 km and 624 m, respectively. The maximum distances at the moderate threshold were reduced to 210 km for summer and 217 km for winter conditions.

Table 9.28 to

Table 9.30 summarise the probability of exposure to individual sensitive receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer for each season. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at their shallowest depth from the sea surface.

A combined total of 7 AMPs are within the low exposure zone across the 3 seasons, with the Montebello AMP recording the highest probability of exposure of 7% during transitional conditions. The shortest time for exposure at the low threshold to an AMP was recorded at Dampier during transitional conditions at 0.88 days (21 hours).

No KEF receptors were predicted to be exposed by entrained hydrocarbons at the low threshold.

Four RSBs are within the low threshold zone across the 3 seasons and the highest probability of exposure was predicted at Rankin Shoal at 7% during transitional conditions, with a corresponding minimum time of 5.6 days before contact.

Entrained hydrocarbons at the low threshold were predicted to cross into WA State Waters during every season with probabilities ranging from 2-6%. The minimum time before oil crossed the WA State Waters boundary was 1.08 days (26 hours), for a spill commencing during transitional conditions.

Table 9.28 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer. Results are based on a subsea release over 1 hour, releasing a total of 1,080 m³ of crude from the export pipeline during summer (October to March) conditions. The results were calculated from 100 spill simulations.

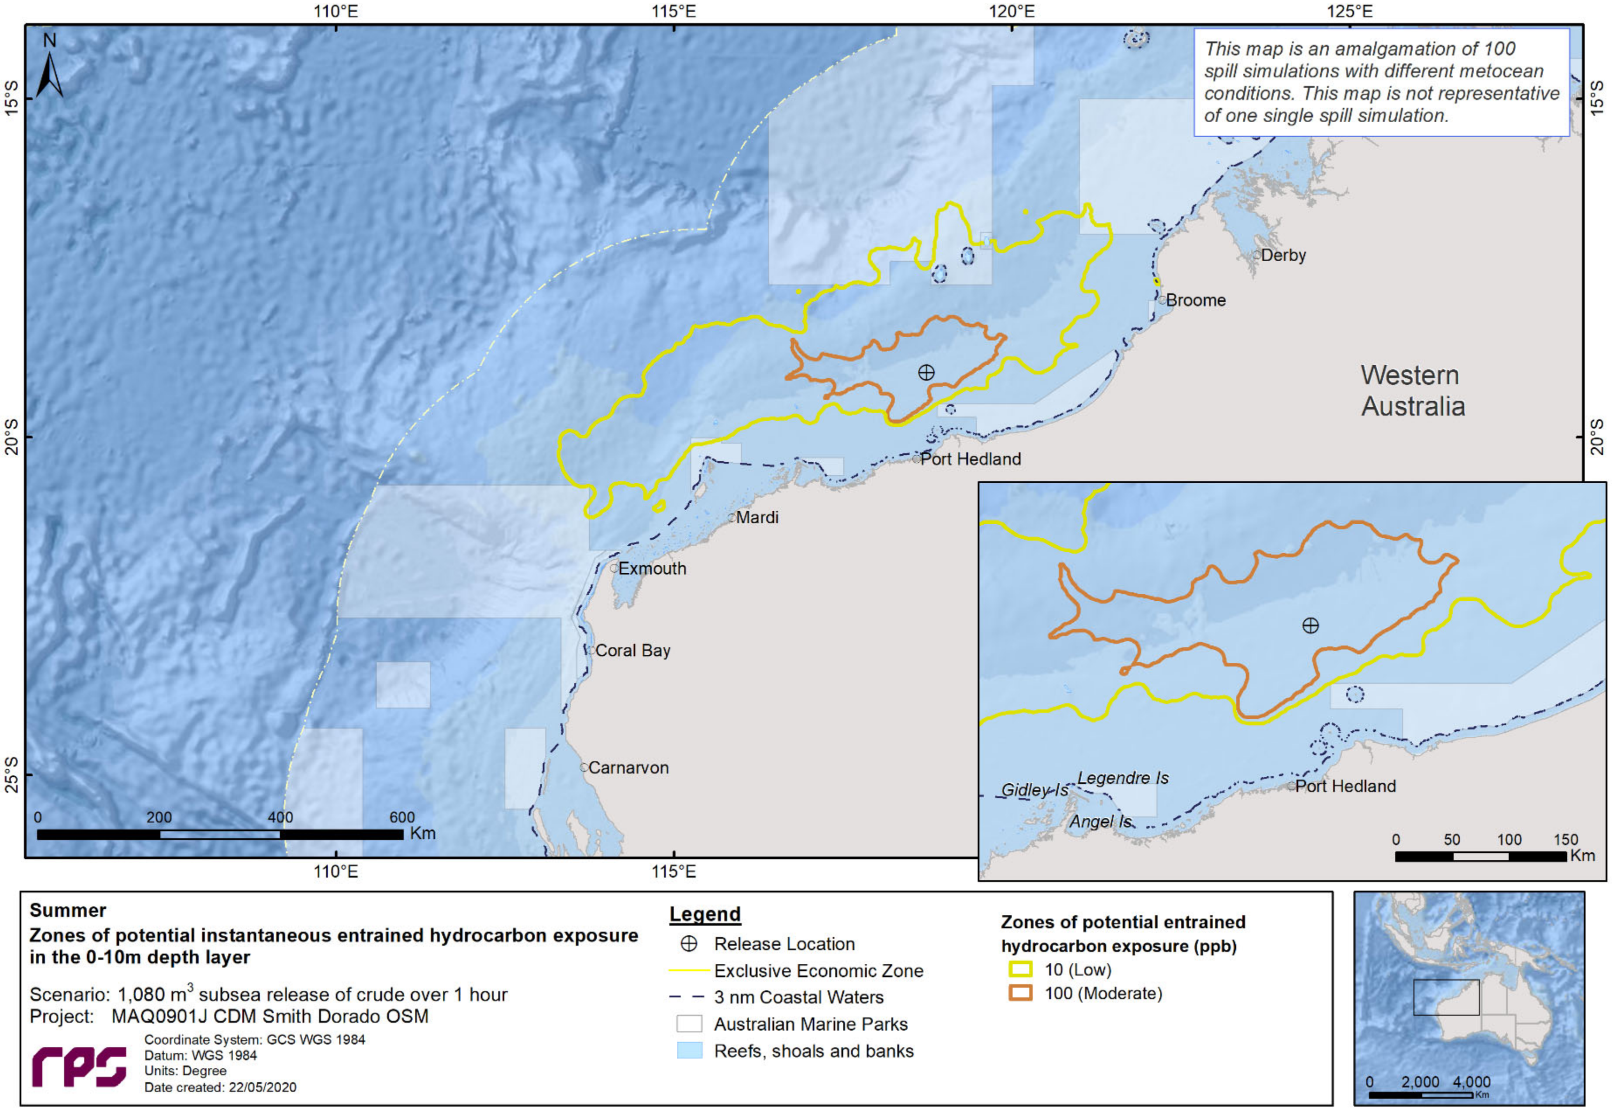

Figure 9.64 Predicted entrained hydrocarbon exposure zones resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

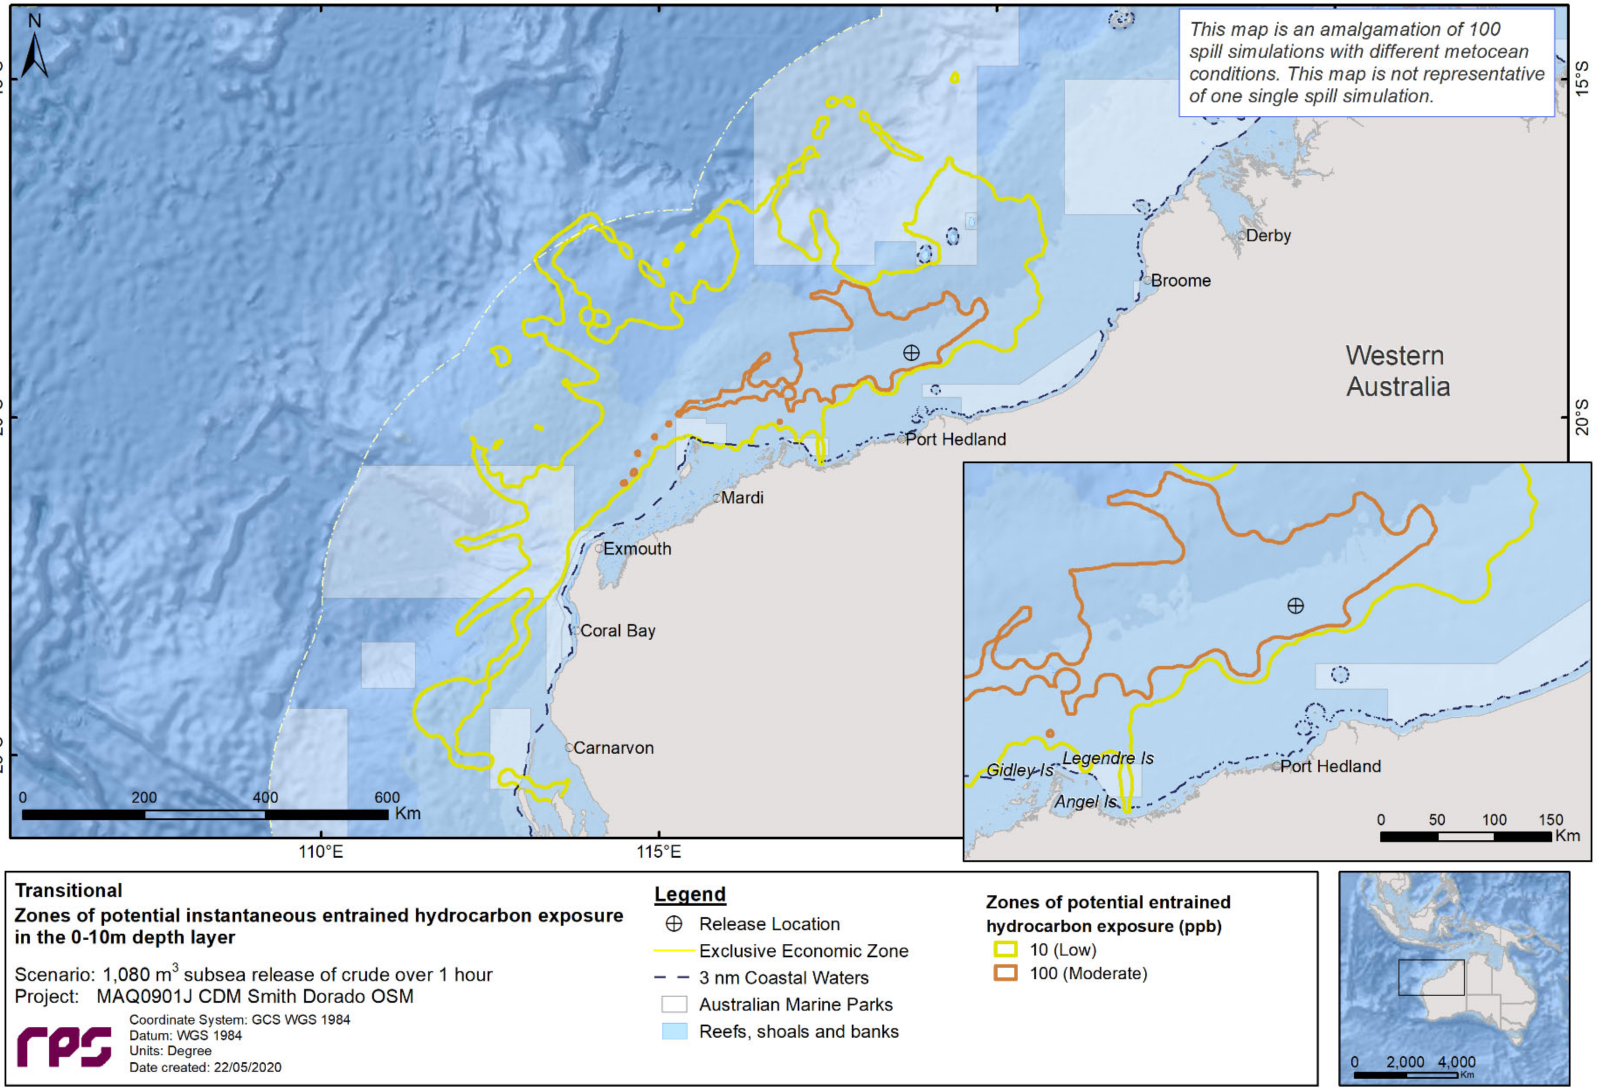

Figure 9.65 Predicted entrained hydrocarbon exposure zones resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

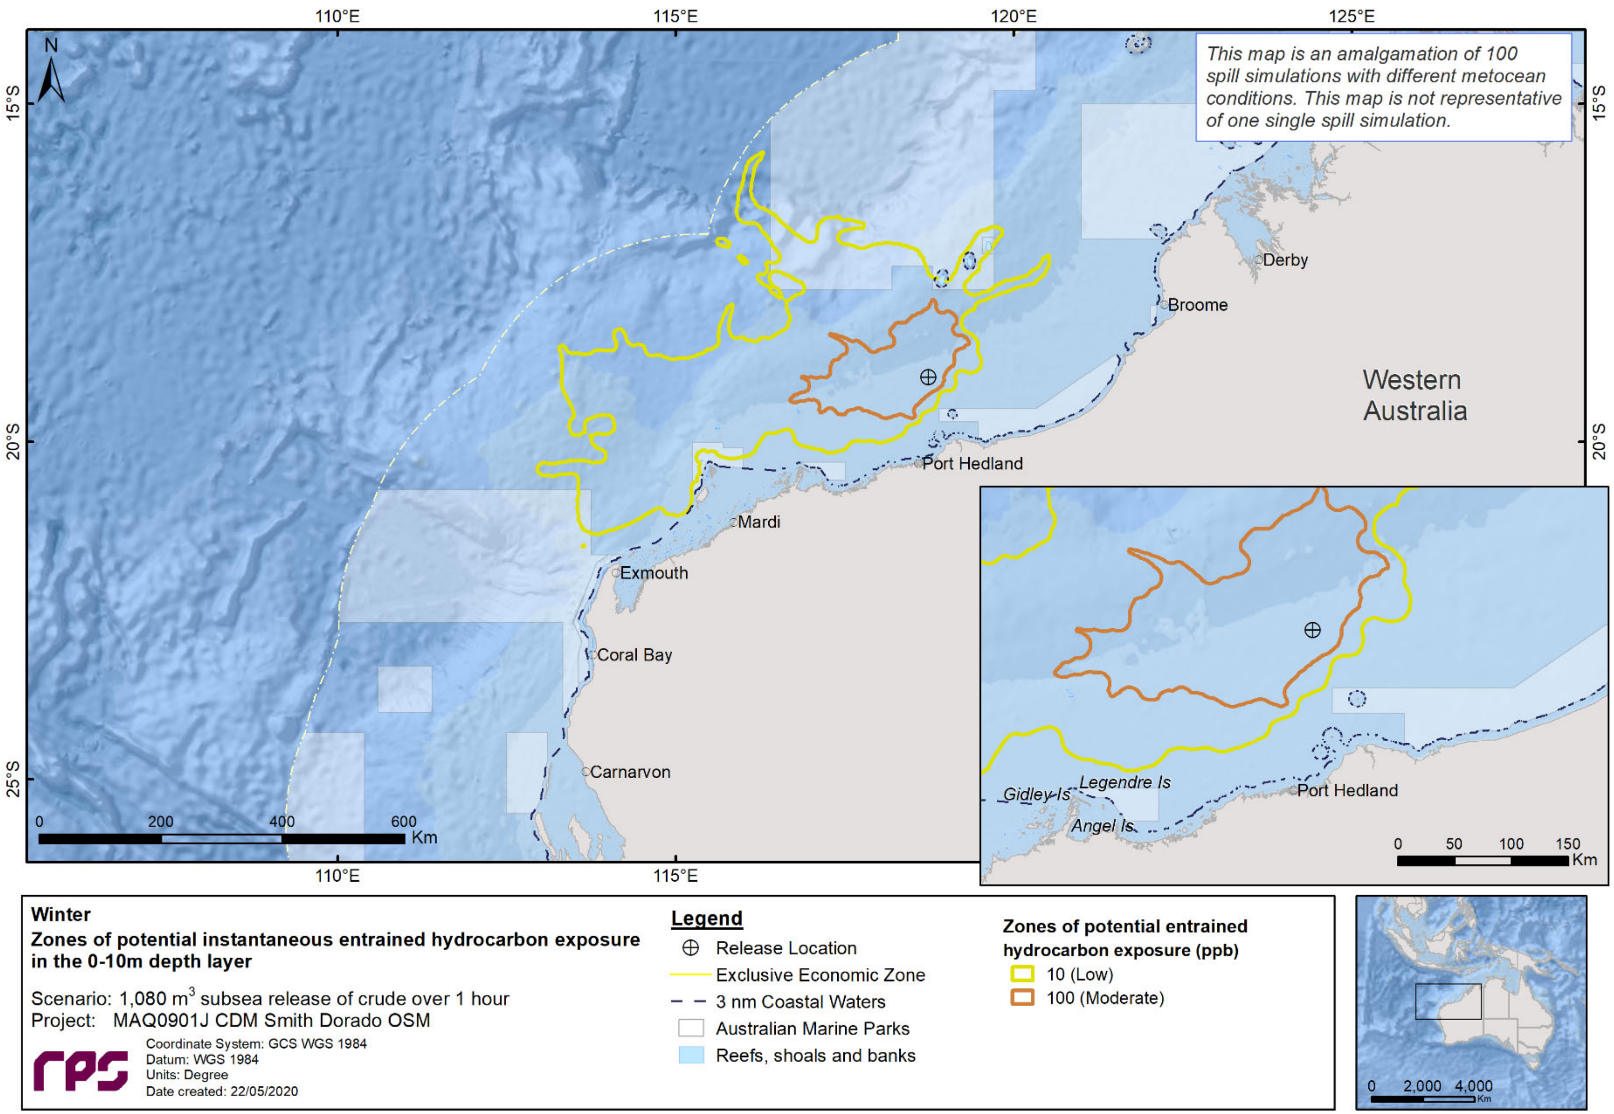

Figure 9.66 Predicted entrained hydrocarbon exposure zones resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.3.3.4 Dissolved Hydrocarbons

Images of dissolved hydrocarbon exposure zones are depicted in Figure 9.67, Figure 9.68and Figure 9.69 for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively. The results indicated that the low threshold (10-50 ppb) extended furthest up to a maximum distance of 28 km (west) from the release location during summer conditions. The maximum distances for transitional and winter conditions at the low threshold were 12 km and 20 m, respectively.

No exposure at the moderate (50-400 ppb) or high (≥ 400 ppb) thresholds was predicted in any of the assessed seasons.

Dissolved hydrocarbons were not predicted to impact any receptors (other than the Northwest Shelf IMCRA, which resides within the release location) at, or above, the low (10-50 ppb) threshold hence no tables are presented for this scenario.

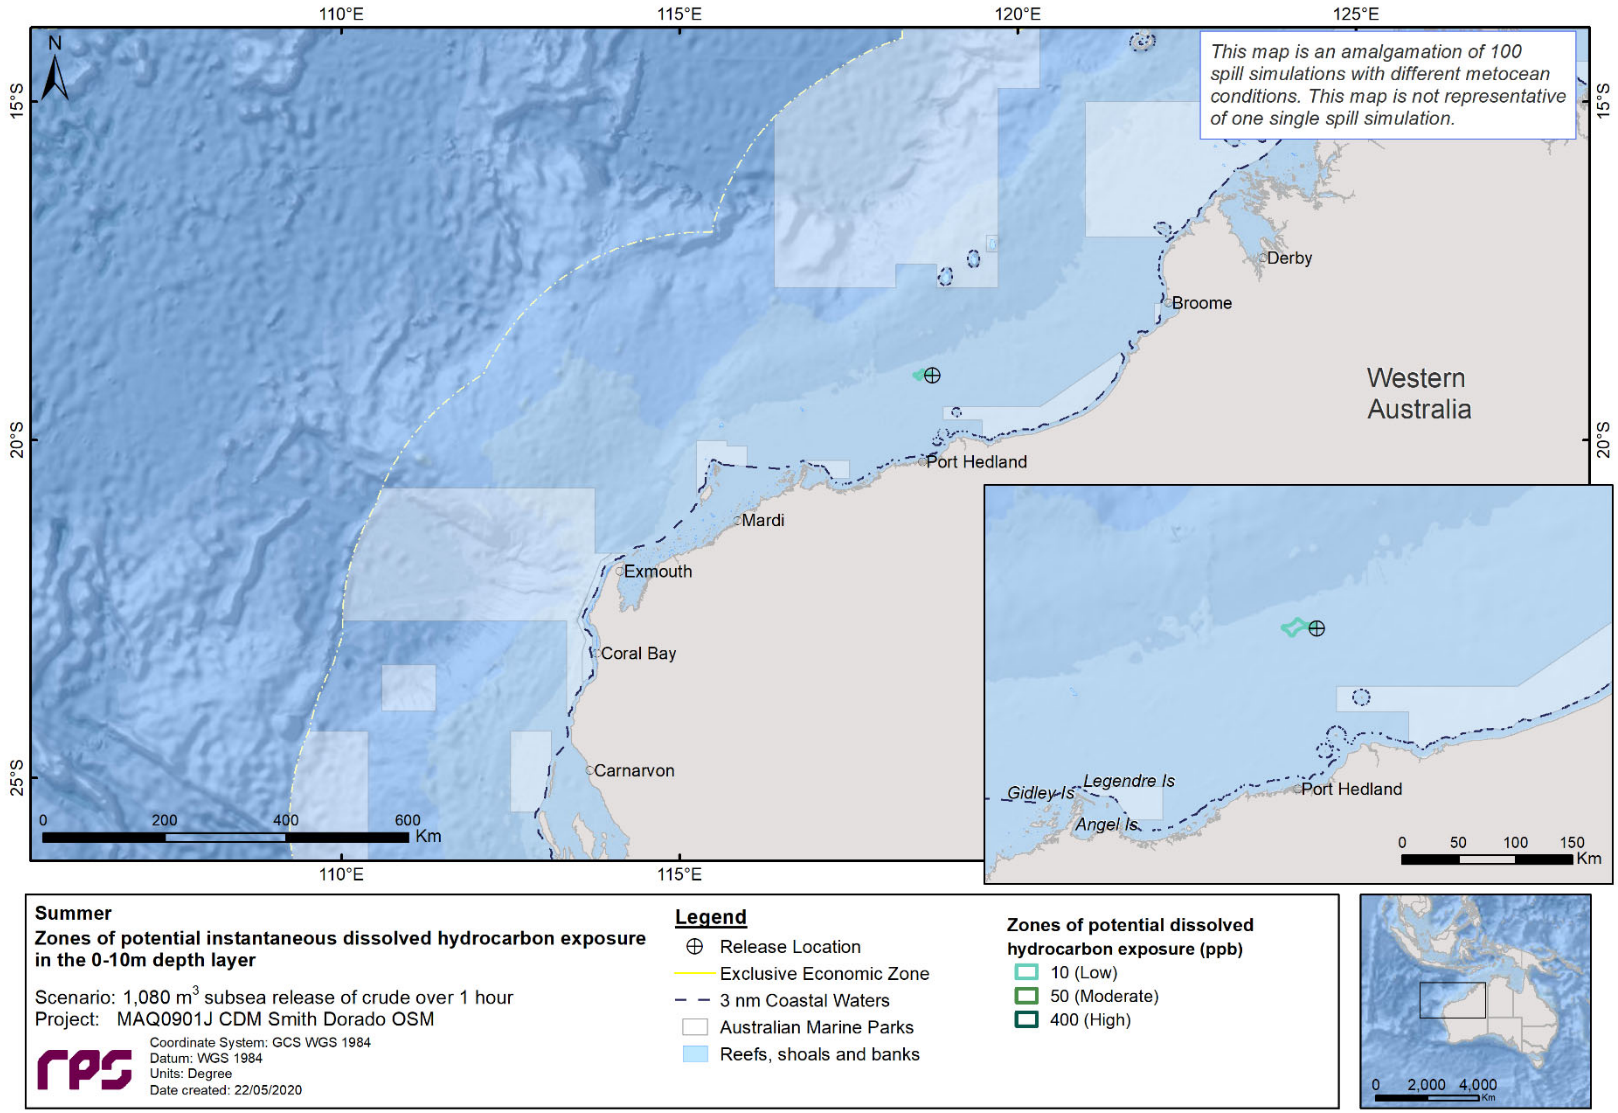

Figure 9.67 Predicted dissolved hydrocarbon exposure zones resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

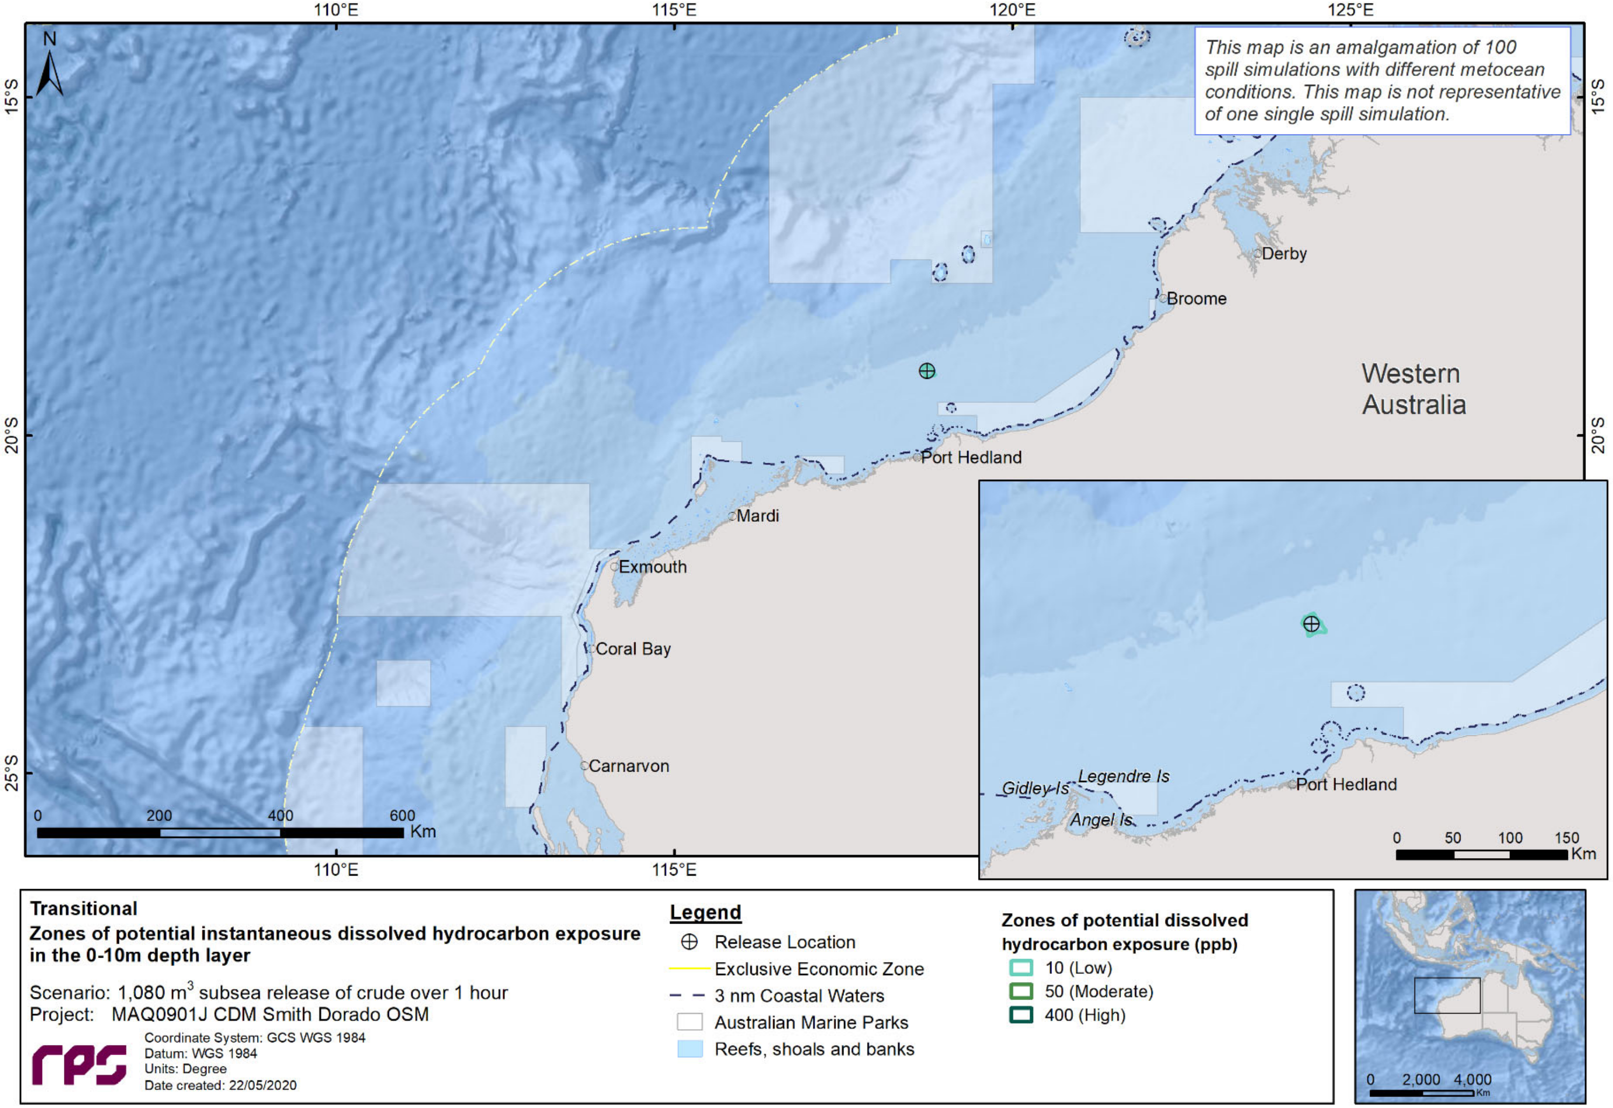

Figure 9.68 Predicted dissolved hydrocarbon exposure zones resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

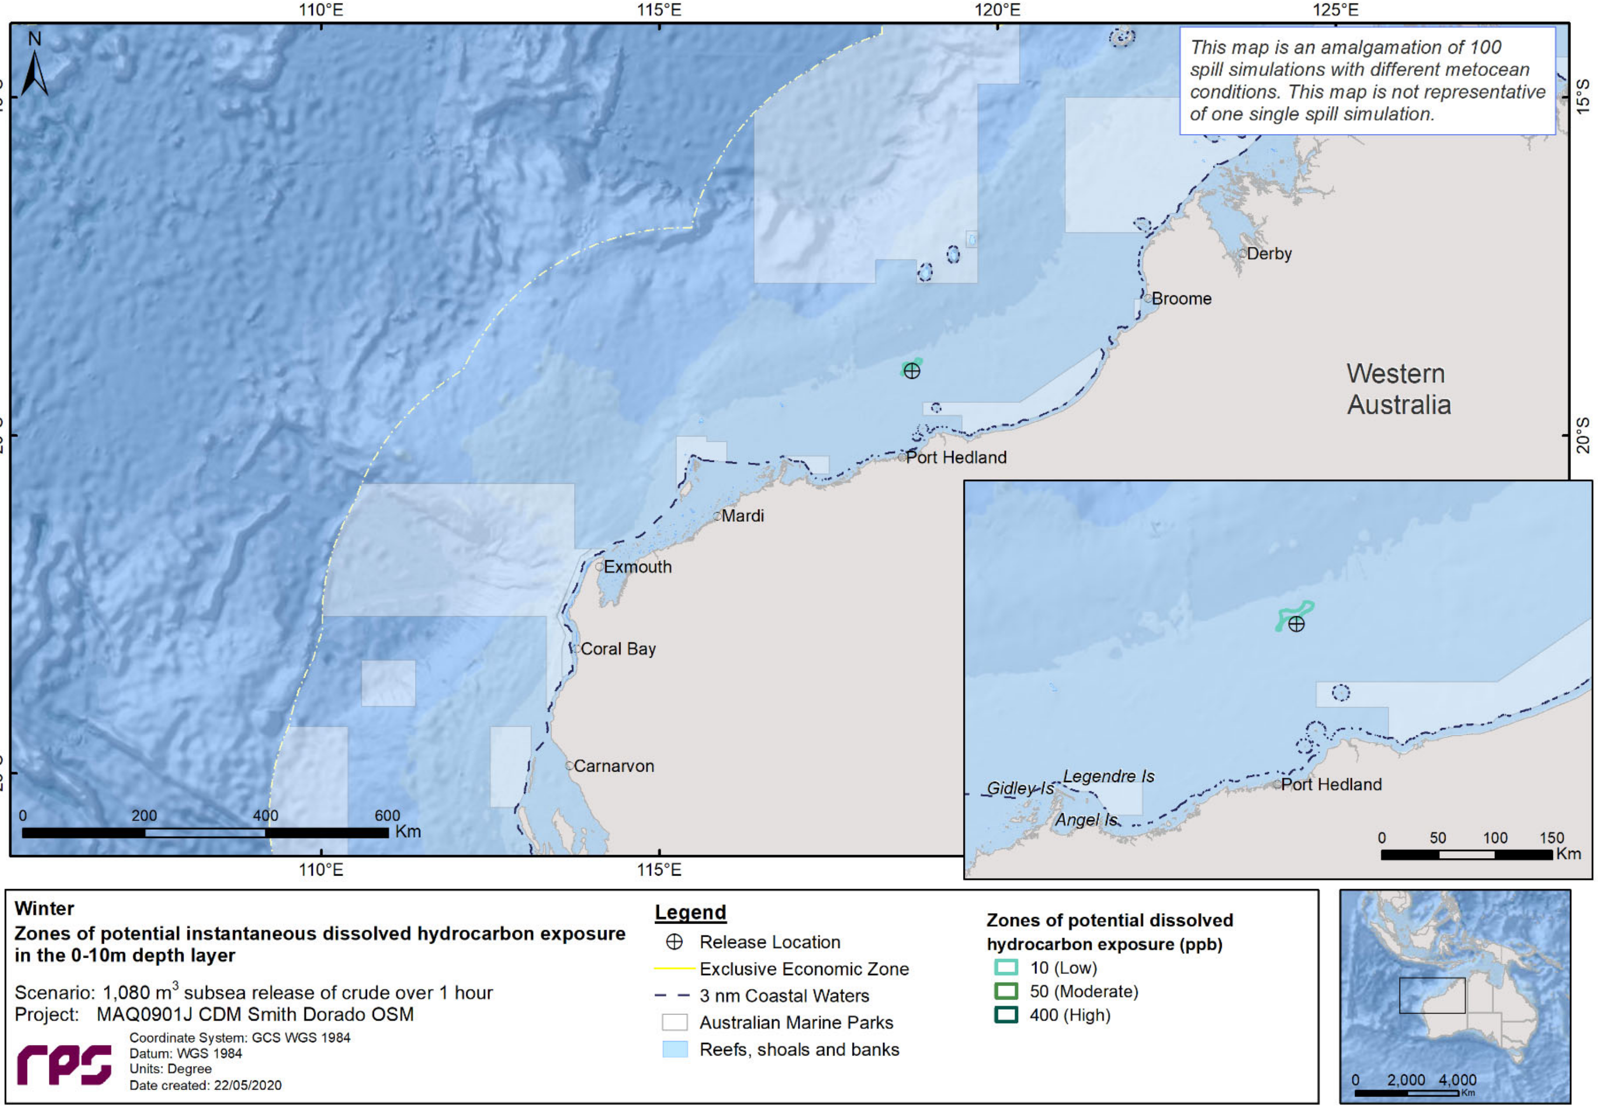

Figure 9.69 Predicted dissolved hydrocarbon exposure zones resulting from a subsea release over 1 hour, releasing a total of 1,080 m^3 of crude from the export pipeline. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.4 Scenario 4: Simulation of an instantaneous surface release of crude at the FPSO due to an offtake incident

This scenario examined an instantaneous 225 m^3 surface release of crude at the FPSO, tracked for 21 days. A total of 300 simulations were run across three seasons; summer, transitional and winter (i.e. 100 spills per season). These are then combined and presented as exposures zones for each season (cumulative of 100 simulations) for the low, moderate and high thresholds.

Sections 9.4.1 presents overview of the EMBA based on combining the 300 spill simulations and Section 9.4.3 shows the seasonal (or stochastic) analysis. As there was no shoreline accumulation predicted for any spills during this scenario, the deterministic analysis results (i.e. a single spill simulation), presented in Section 9.4.2 are based on the largest area of floating oil (above 50 g/m^2) and the largest area of entrained hydrocarbons.

9.4.1 Overview

Figure 9.70 and Figure 9.71 are maps which encompass the full geographic EMBA derived by overlaying the combined results from all 300 spill simulations at both the low and moderate exposure thresholds, respectively.

Figure 9.72 and Figure 9.73 show the annualised extent of floating oil and in-water (entrained and dissolved) exposure based on the low and moderate exposure thresholds, respectively, derived from combining all 300 spill simulations.

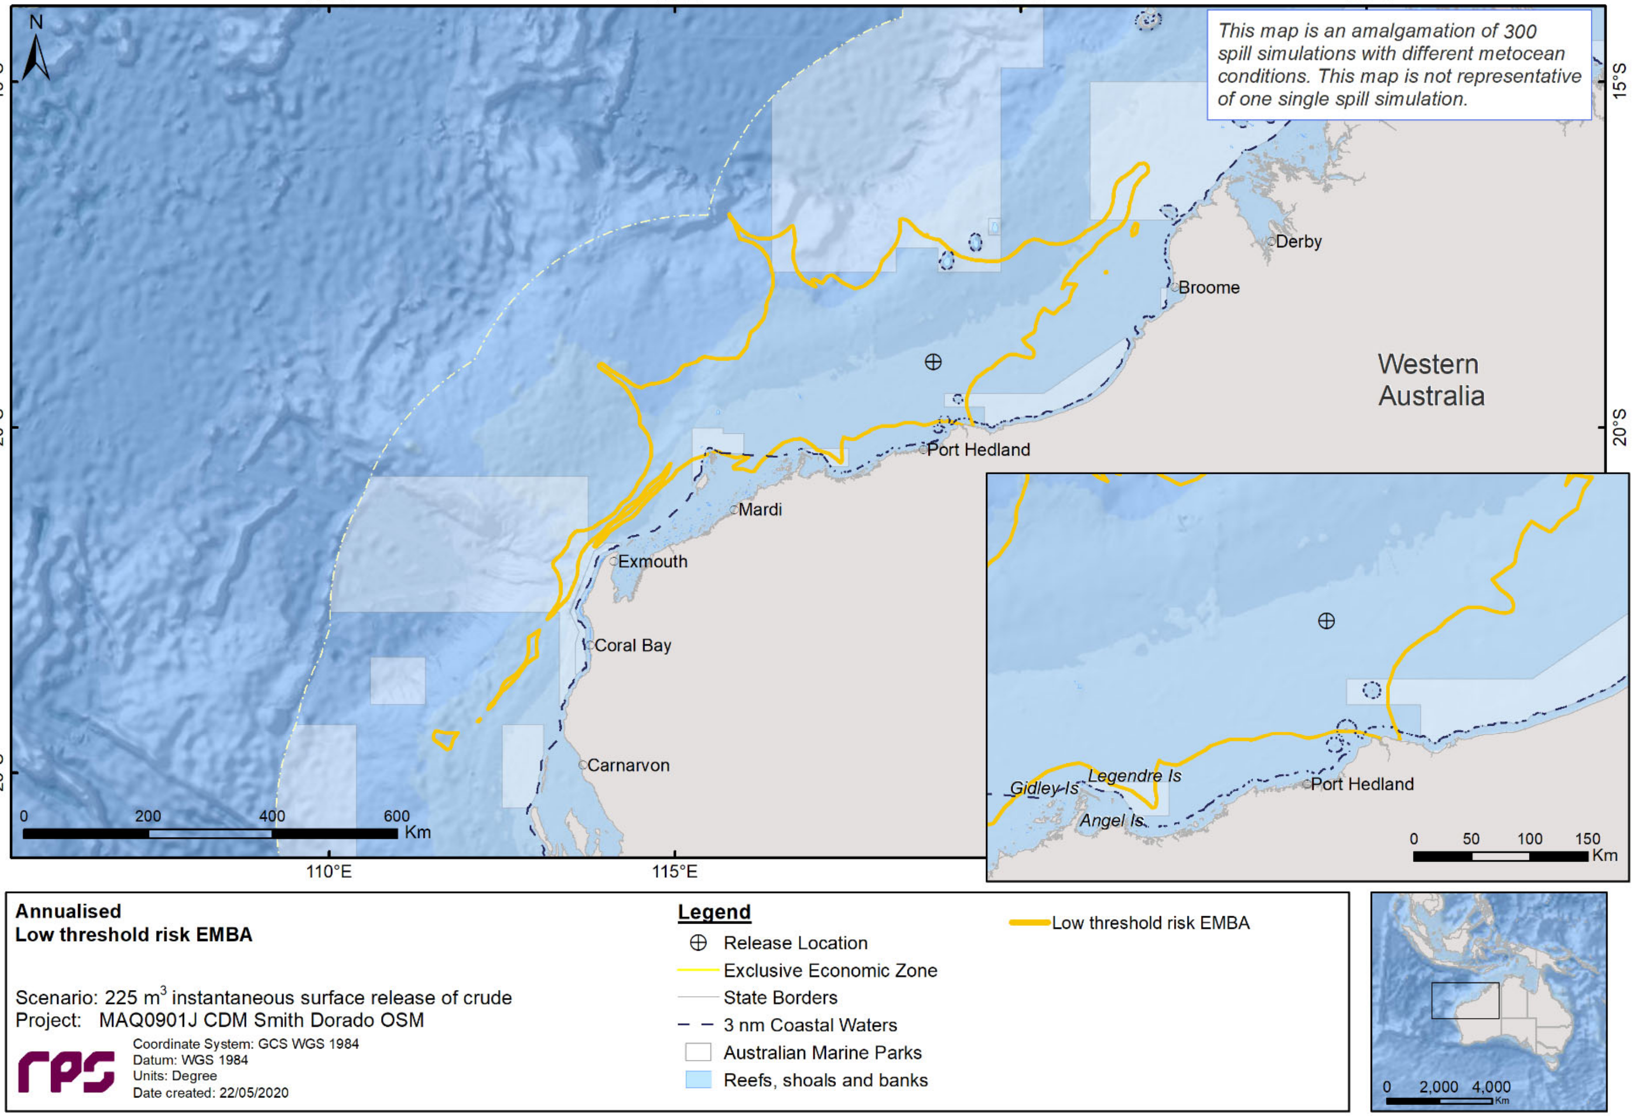

Figure 9.70 Predicted low threshold risk EMBA resulting from an instantaneous surface release of 225 m^3 of crude at the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 21 days.

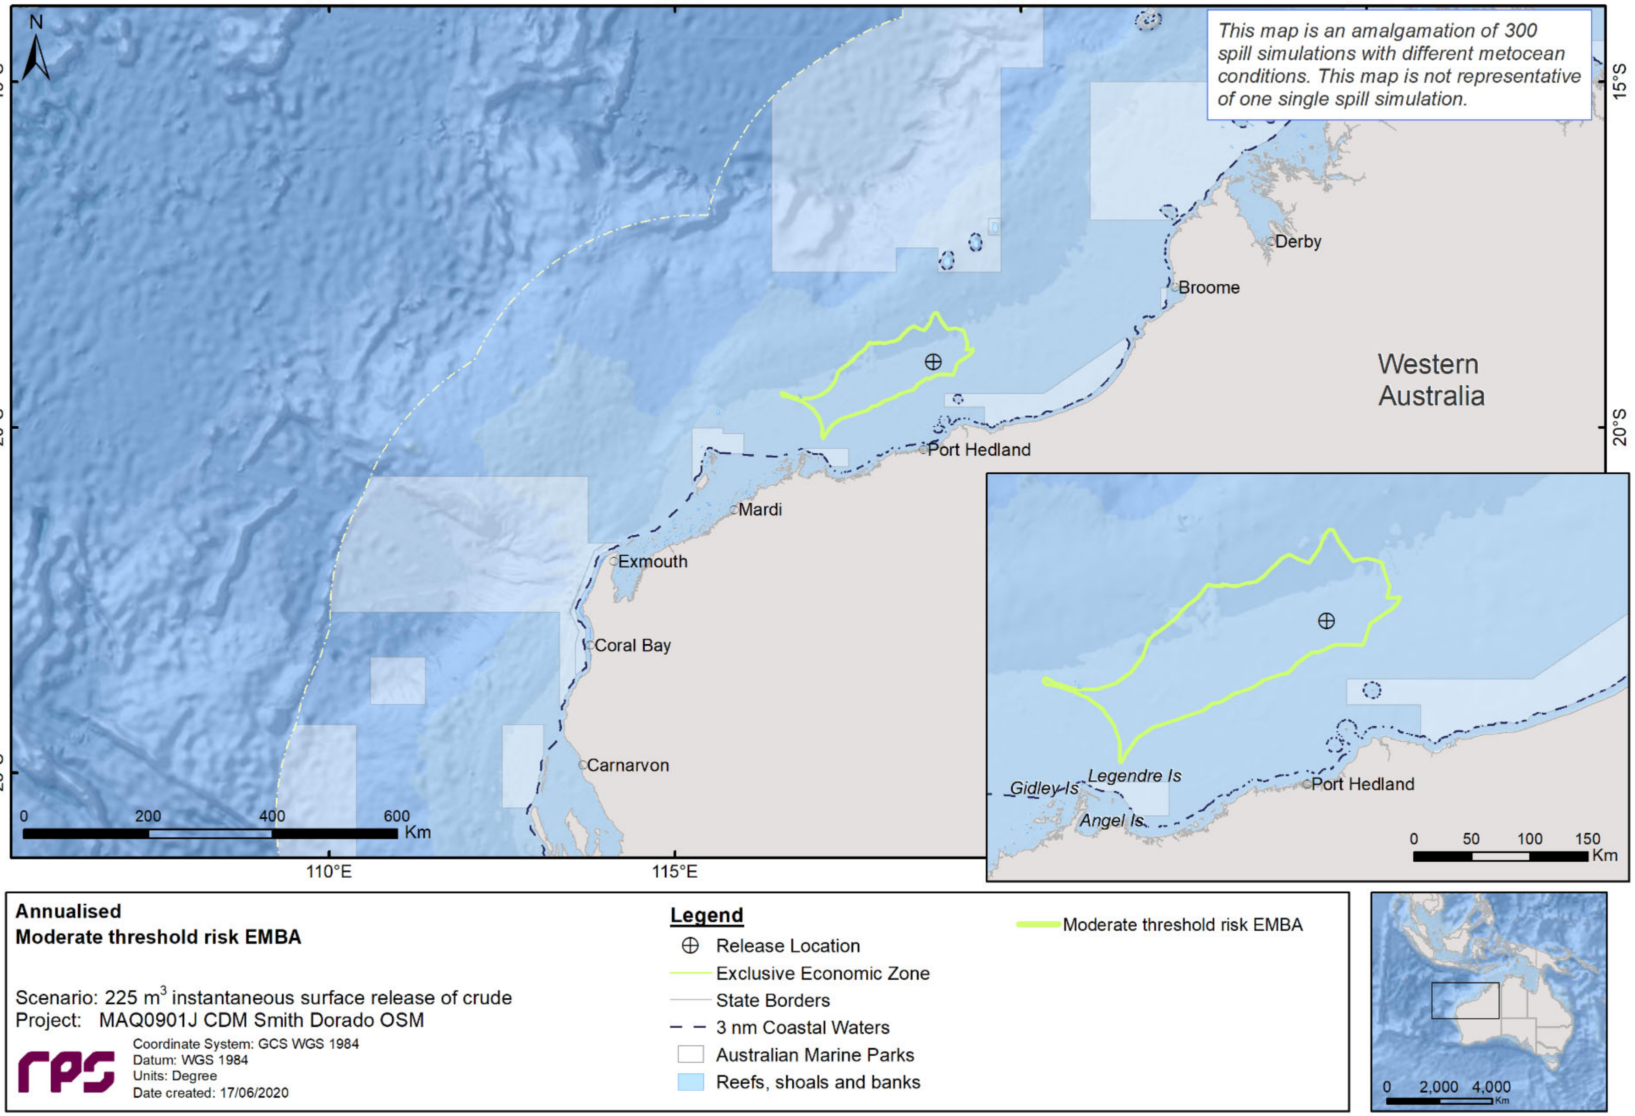

Figure 9.71 Predicted moderate threshold risk EMBA resulting from an instantaneous surface release of 225 m³ of crude at the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 21 days.

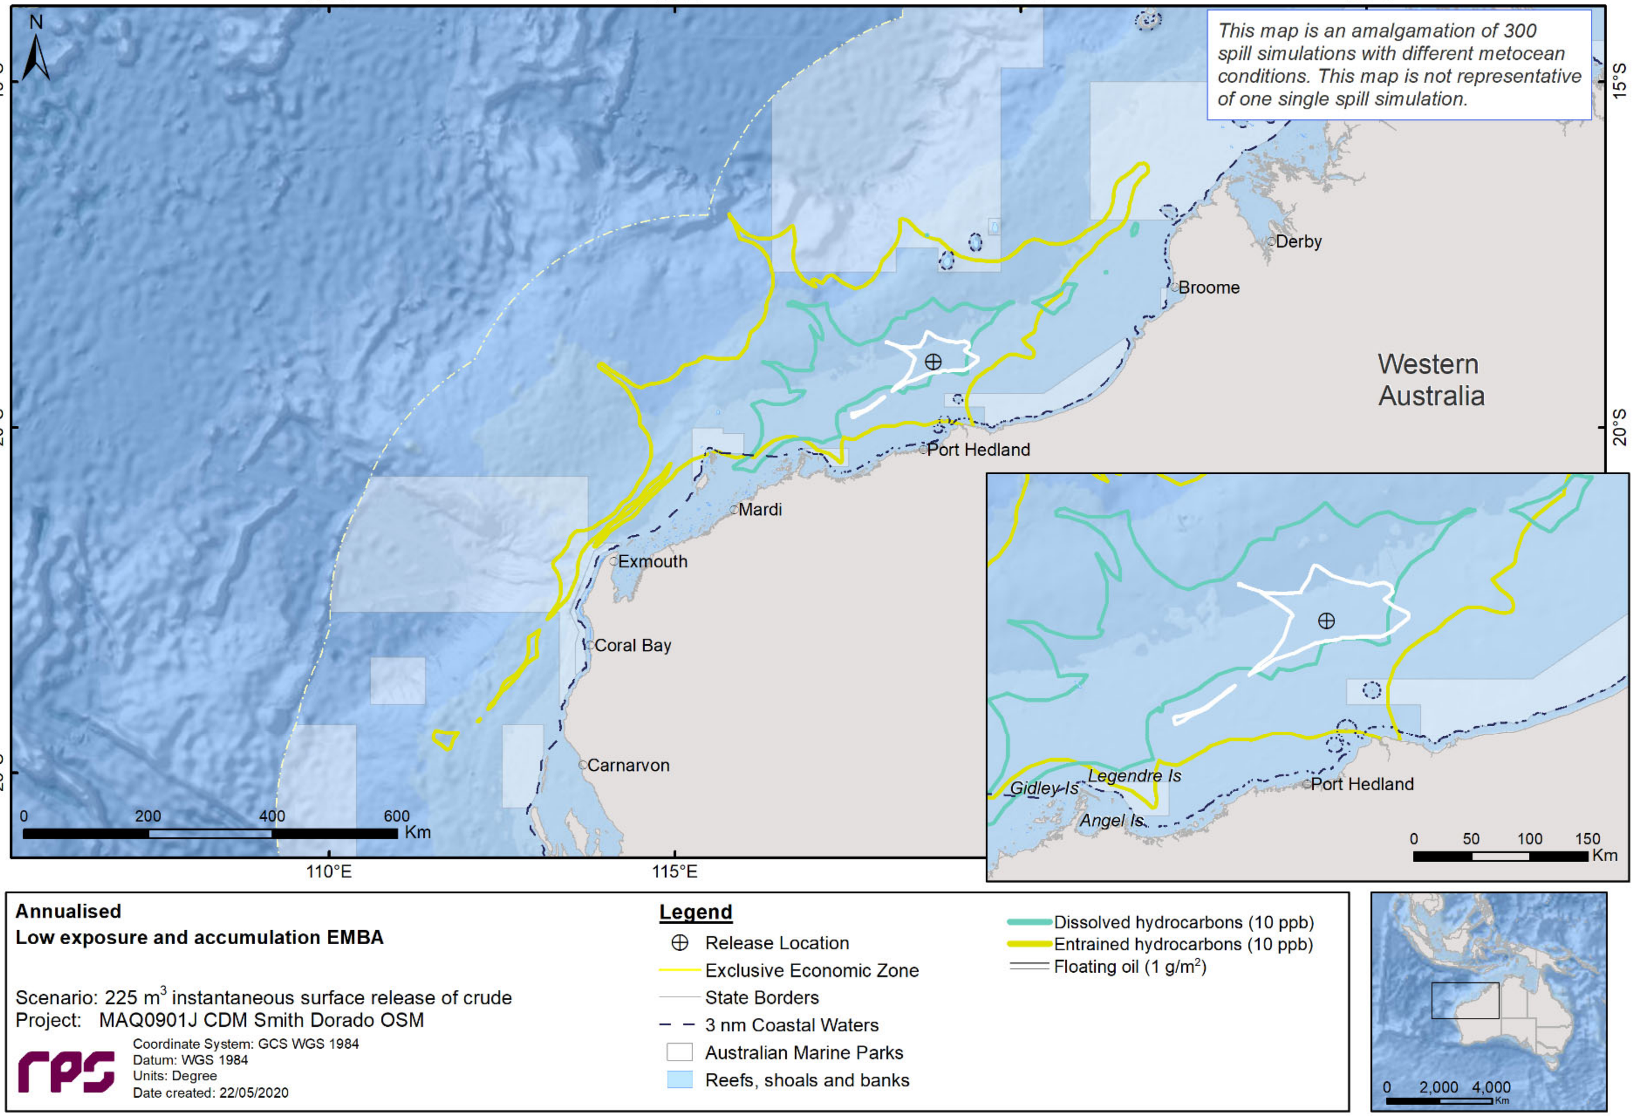

Figure 9.72 Annualised low threshold oil exposure resulting from an instantaneous surface release of 225 m^3 of crude at the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 21 days.

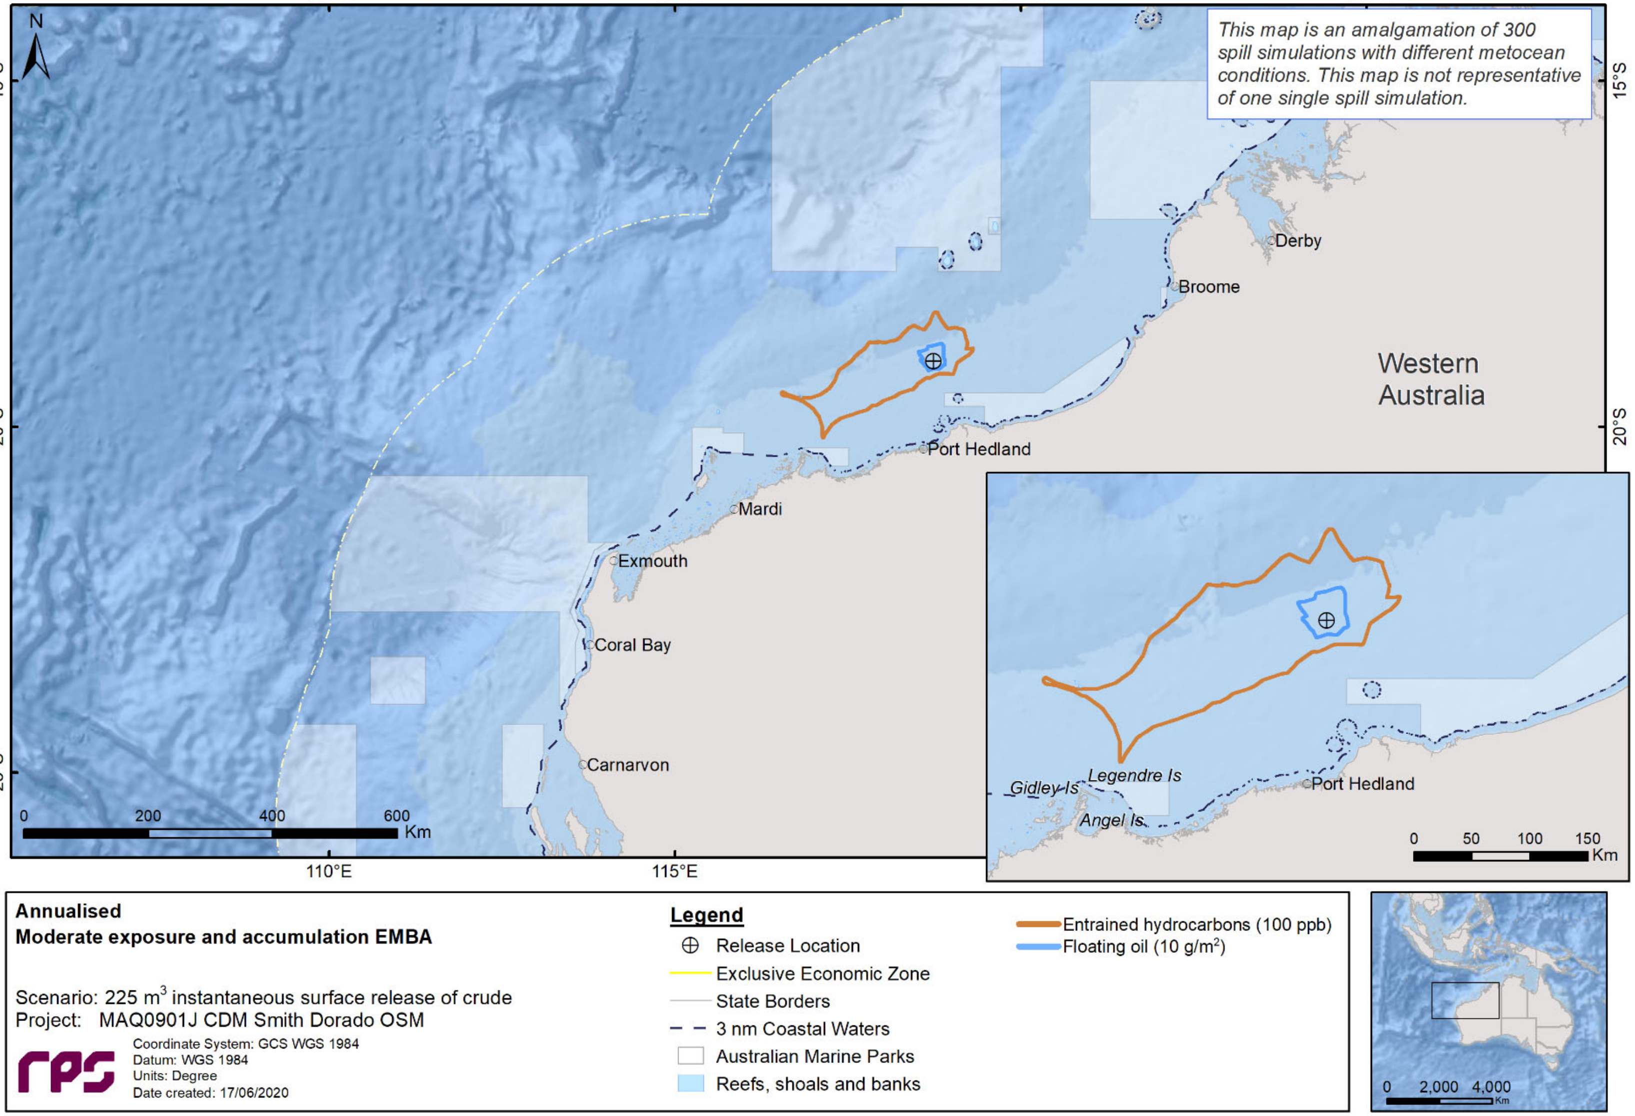

Figure 9.73 Annualised moderate threshold oil exposure resulting from an instantaneous surface release of 225 m^3 of crude at the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 21 days.

9.4.2 Deterministic Analysis

The stochastic modelling results were assessed and the deterministic runs were identified and presented below based on the following criteria;

a. Largest area of floating oil above 50 g/m^2 (actionable floating oil); and

b. Largest area of entrained hydrocarbon exposure

9.4.2.1 Deterministic Case: Largest Area of Floating Oil above 50 g/m^2

The deterministic simulation that resulted in the largest area of floating oil above 50 g/m^2 (high or actionable floating oil threshold) was identified during transitional conditions as run number 44, which commenced at 5 am on the 6th of September 2016.

Exposure from floating oil (swept area) over the entire 21 day simulation is presented in Figure 9.74. Floating oil exposure was predicted north-northeast from the release location up to a maximum distance of approximately 15 km at the low (1-10 g/m^2) threshold. Floating oil at the moderate threshold (10-50 g/m^2) threshold was predicted to extend a maximum distance of approximately 10 km north of the release location, while at the high (≥50 g/m^2) threshold the extent remained within 8 km of the release location.

Figure 9.75 displays the time series of the area of visible oil (≥1 g/m^2) and actionable floating oil (≥50 g/m^2) exposure on the sea surface over the 21-day simulation. The maximum area of coverage of visible oil on the sea surface was predicted to occur 0.75 days (18 hours) after the spill started and covered approximately 6 km^2.

Figure 9.76 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 152 m^3 (68%) spilled oil was lost to the atmosphere through evaporation. Approximately 28 m^3 (12%) of the crude was predicted to have decayed, while approximately 45 m^3 (20%) was predicted to remain within the water column.

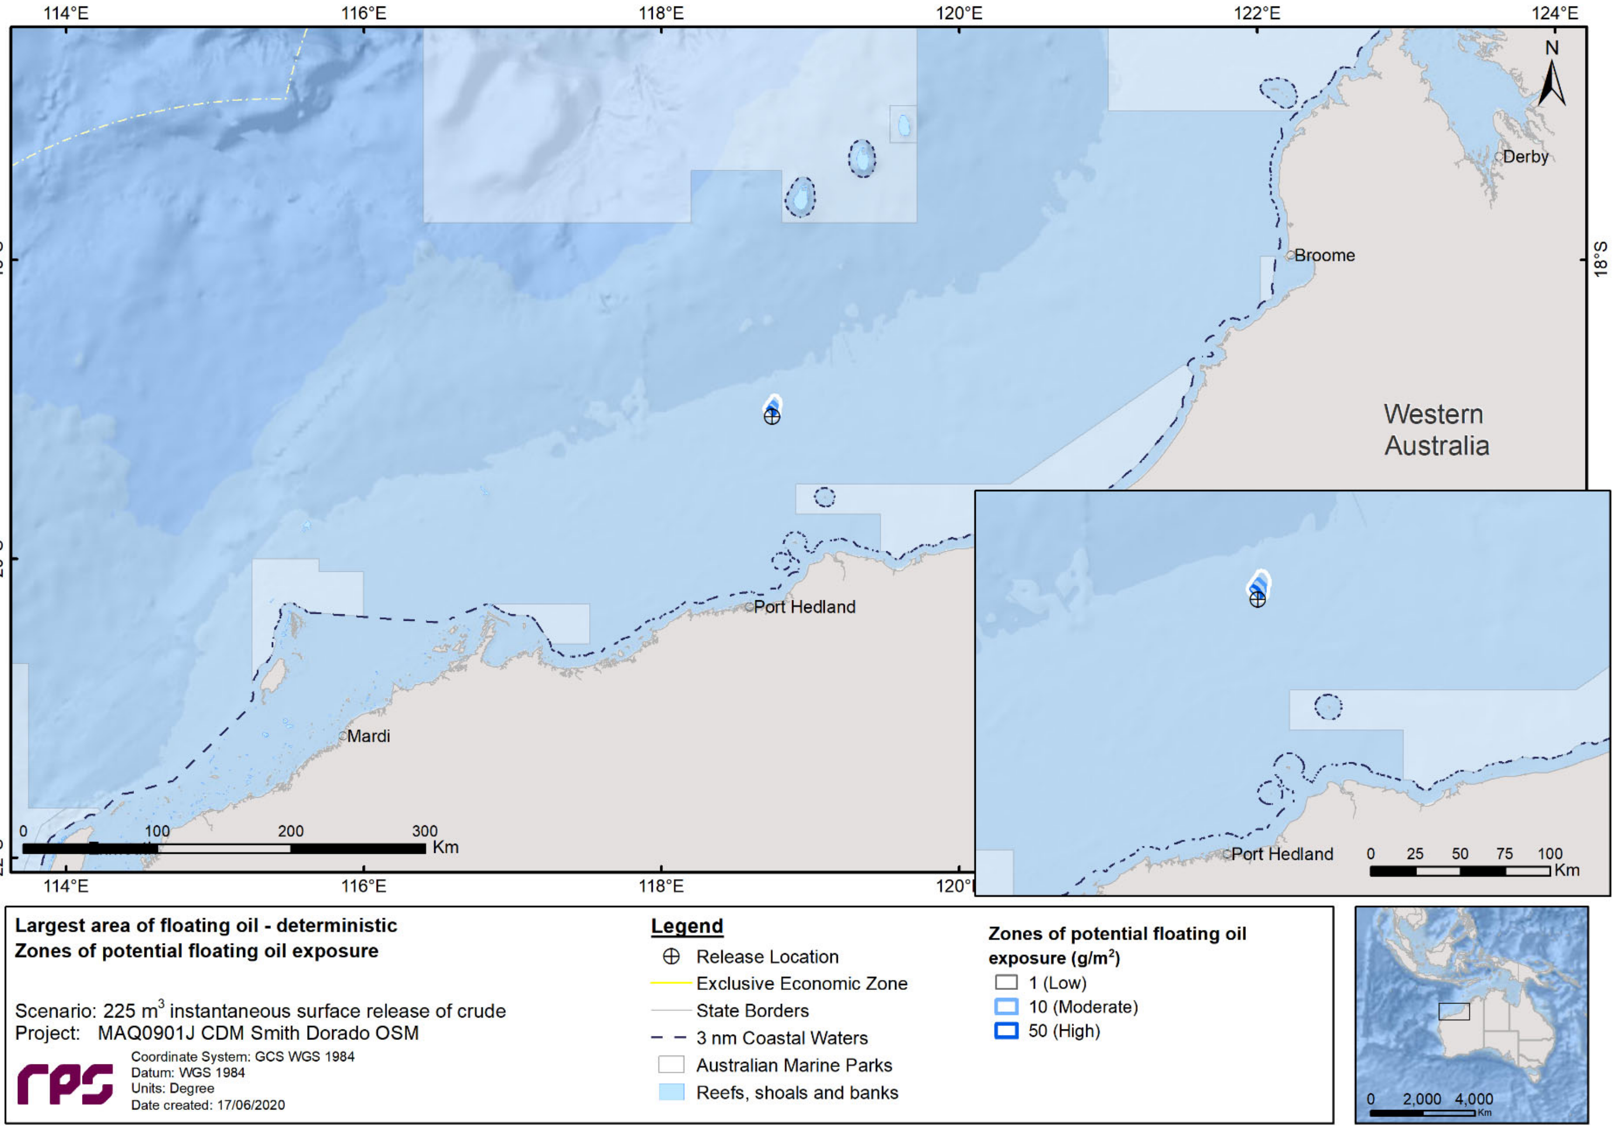

Figure 9.74 Exposure from floating oil (over the 21 day simulation) for the simulation with the largest area of floating oil above 50 g/m^2. Results are based on an instantaneous surface release of 225 m^3 of crude at the FPSO, starting 5 am on the 6th of September 2016.

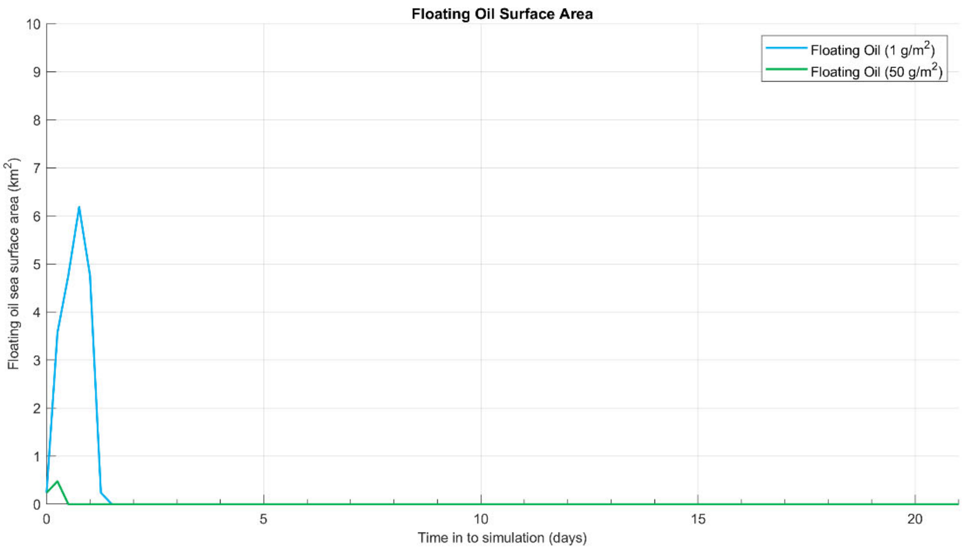

Figure 9.75 **Time series of the area of visible (≥1 g/m²) and actionable floating oil (≥50 g/m²) on the sea surface for the simulation with the largest area of floating oil above 50 g/m². Results are based on an instantaneous surface release of 225 m³ of crude at the FPSO, tracked for 21 days, 5 am on the 6th of September 2016.**

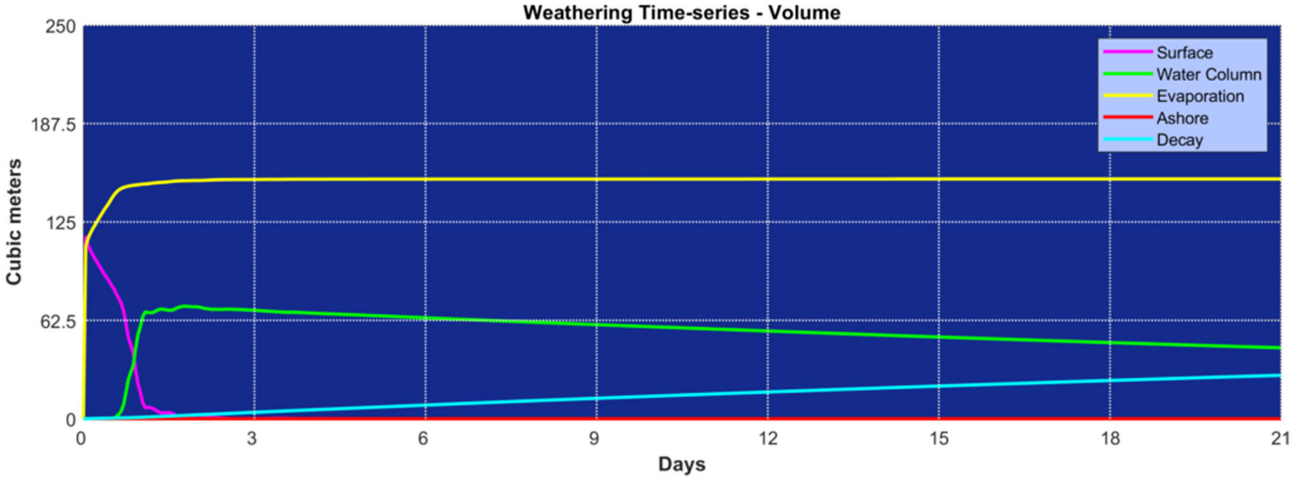

Figure 9.76 **Predicted weathering and fates graph for the single spill simulation with the largest area of floating oil above 50 g/m². Results are based on an instantaneous surface release of 225 m³ of crude at the FPSO, tracked for 21 days, 5 am on the 6th of September 2016.**

9.4.2.2 Deterministic Case: Largest Area of Entrained Hydrocarbons

The deterministic simulation that resulted in the largest area of entrained hydrocarbons was identified during transitional conditions as run number 88, which commenced at 8 pm on the 2nd of April 2012.

Exposure from floating oil (swept area) over the entire 21 day simulation are presented in Figure 9.77. The exposure from floating oil was predicted to be within 15 km of the release location.

Figure 9.78 presents the predicted entrained hydrocarbon exposure zones in the 0-10 m depth layer for the entire simulation. Entrained hydrocarbons at the low threshold (10-100 ppb) were predicted to extend a maximum distance of approximately 490 km west from the release location and approximately 23 km at the high threshold.

No dissolved hydrocarbon exposure above the low (10-50 ppb) threshold was predicted for this simulation.

Figure 9.79 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 150 m^3 (66%) spilled oil was lost to the atmosphere through evaporation. Approximately 28 m^3 (12%) of the crude was predicted to have decayed, while approximately 48 m^3 (21%) was predicted to remain within the water column.

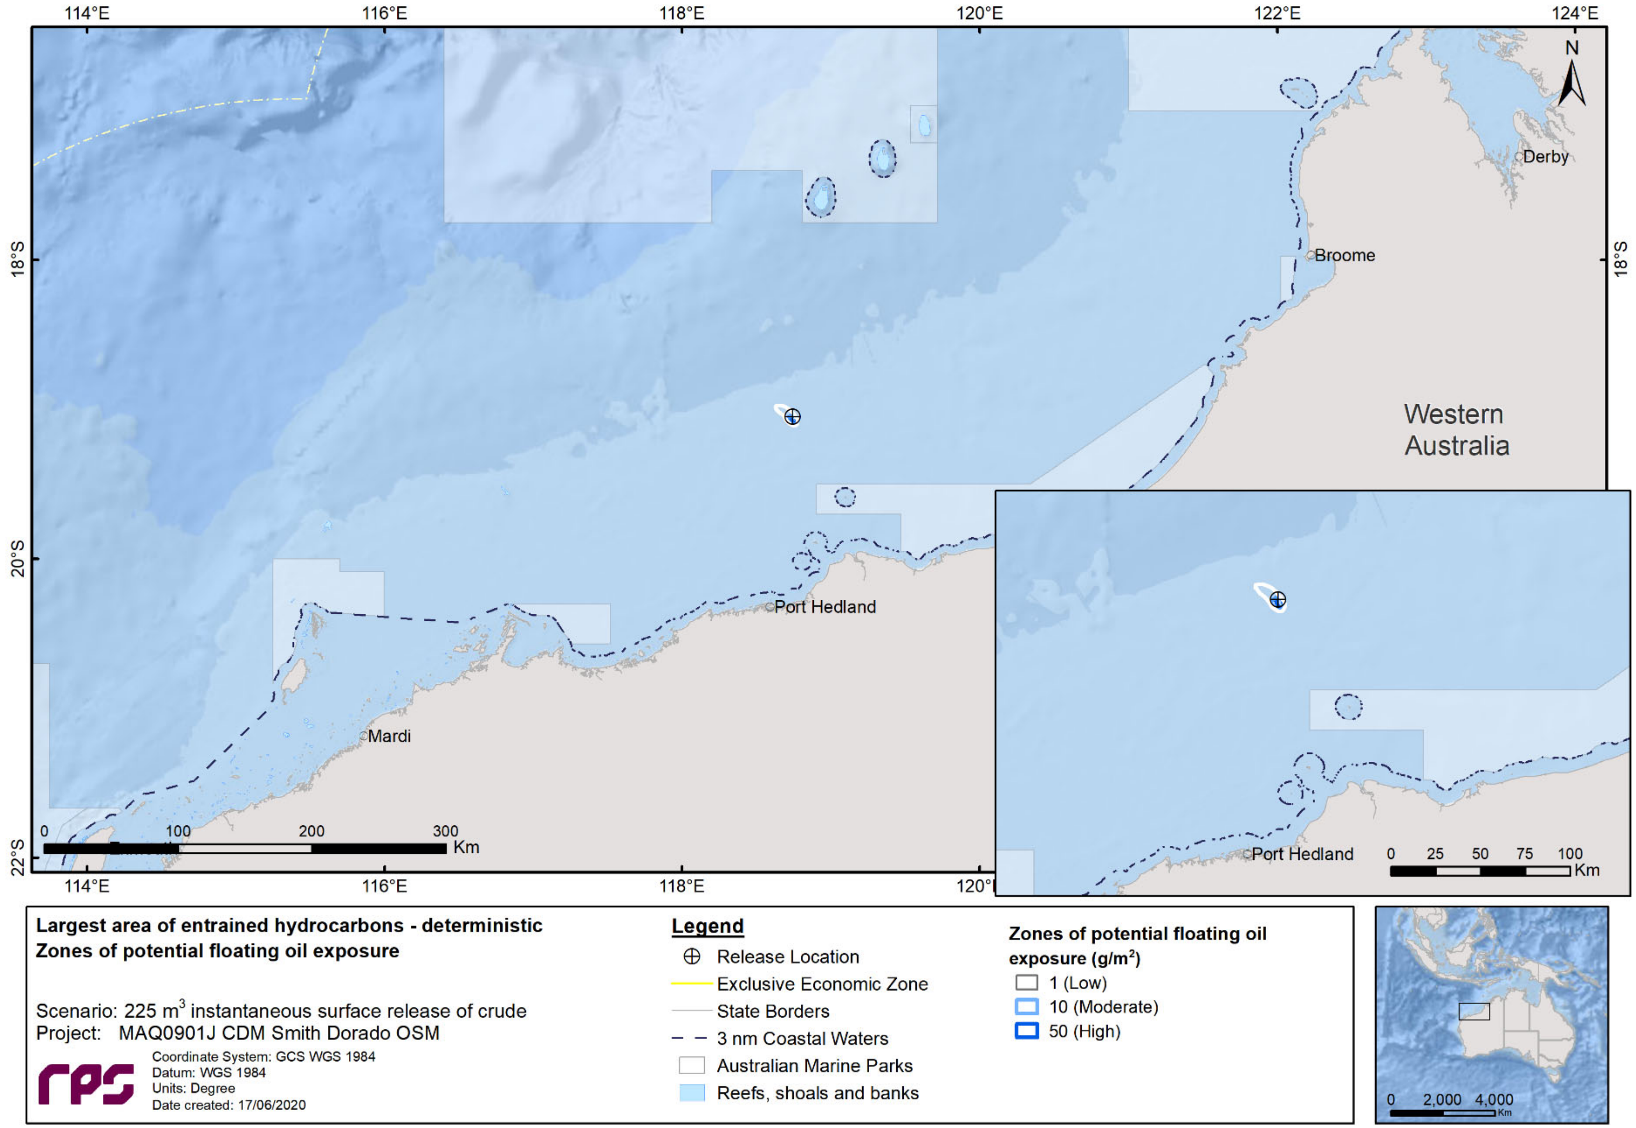

Figure 9.77 Exposure from floating oil (over the 21 day simulation) for the simulation with the largest area of entrained hydrocarbons. Results are based on an instantaneous surface release of 225 m^3 of crude at the FPSO, starting 8 pm on the 2nd of April 2012.

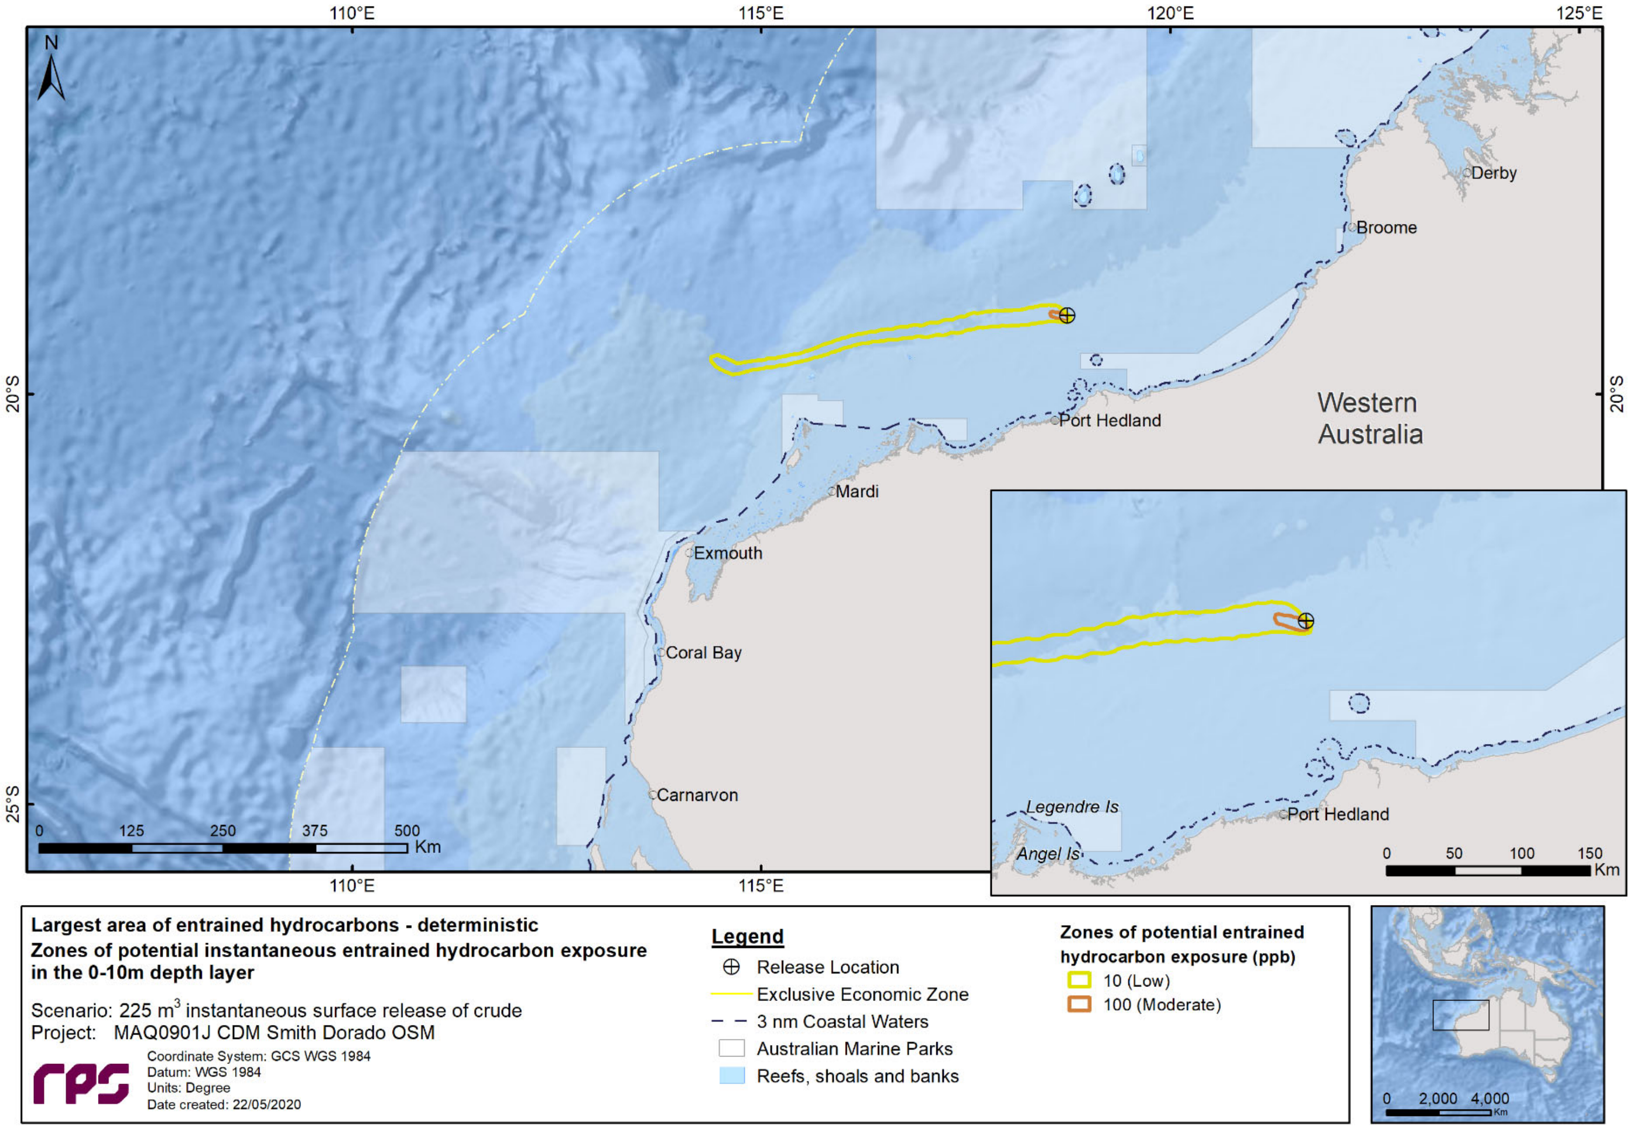

Figure 9.78 Predicted entrained hydrocarbon exposure zones in the 0-10 m depth layer for the simulation with the largest area of entrained hydrocarbons. Results are based on an instantaneous surface release of 225 m^3 of crude at the FPSO, tracked for 21 days, 8 pm on the 2nd of April 2012.

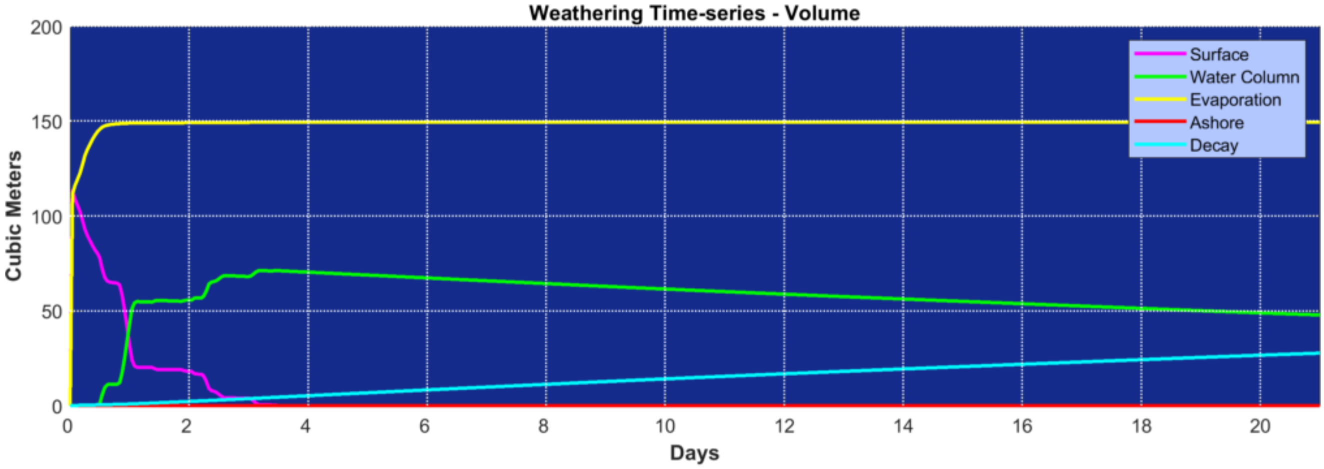

Figure 9.79 Predicted weathering and fates graph for the single spill simulation with the largest area of entrained hydrocarbons. Results are based on an instantaneous surface release of 225 m^3 of crude at the FPSO, tracked for 21 days, 8 pm on the 2nd of April 2012.

9.4.3 Seasonal analysis

9.4.3.1 Floating Oil Exposure

Table 9.31 summarises the maximum distances from the release location to floating oil exposure zones for each season. The maximum distance from the release location to the low (1–10 g/m^2), moderate (10–50 g/m^2) and high (≥ 50 g/m^2) exposure thresholds was 151.8 km southwest (transitional), 30.2 km north-northeast (winter) and 17.2 km northwest (summer), respectively.

Images of floating oil exposure zones are depicted in Figure 9.80, Figure 9.81 and Figure 9.82 for the combined 100 spills commencing during summer, transitional and winter conditions, respectively.

There was no floating oil exposure to any of the receptors assessed.

Table 9.31 Maximum distance and direction from the release location to floating oil exposure thresholds. Results are based on an instantaneous surface release of 225 m^3 of crude at the FPSO. The results were calculated from 100 spill simulations per season.

Season	Distance and direction	Exposure from floating oil		
		Low (1-10 g/m^2)	Moderate (10-50 g/m^2)	High (≥50 g/m^2)
Summer	Max. distance from release site (km)	78.1	27.5	17.2
	Max distance from release site (km) (99th percentile)	36.3	19.6	11.9
	Direction	West-Northwest	West-Northwest	Northwest
Transitional	Max. distance from release site (km)	151.8	19.7	11.6
	Max distance from release site (km) (99th percentile)	54.1	15.3	11.2
	Direction	Southwest	West	Northwest
Winter	Max. distance from release site (km)	66.3	30.2	11.2
	Max distance from release site (km) (99th percentile)	54.3	25.8	10.6
	Direction	East	North-Northeast	North-Northwest

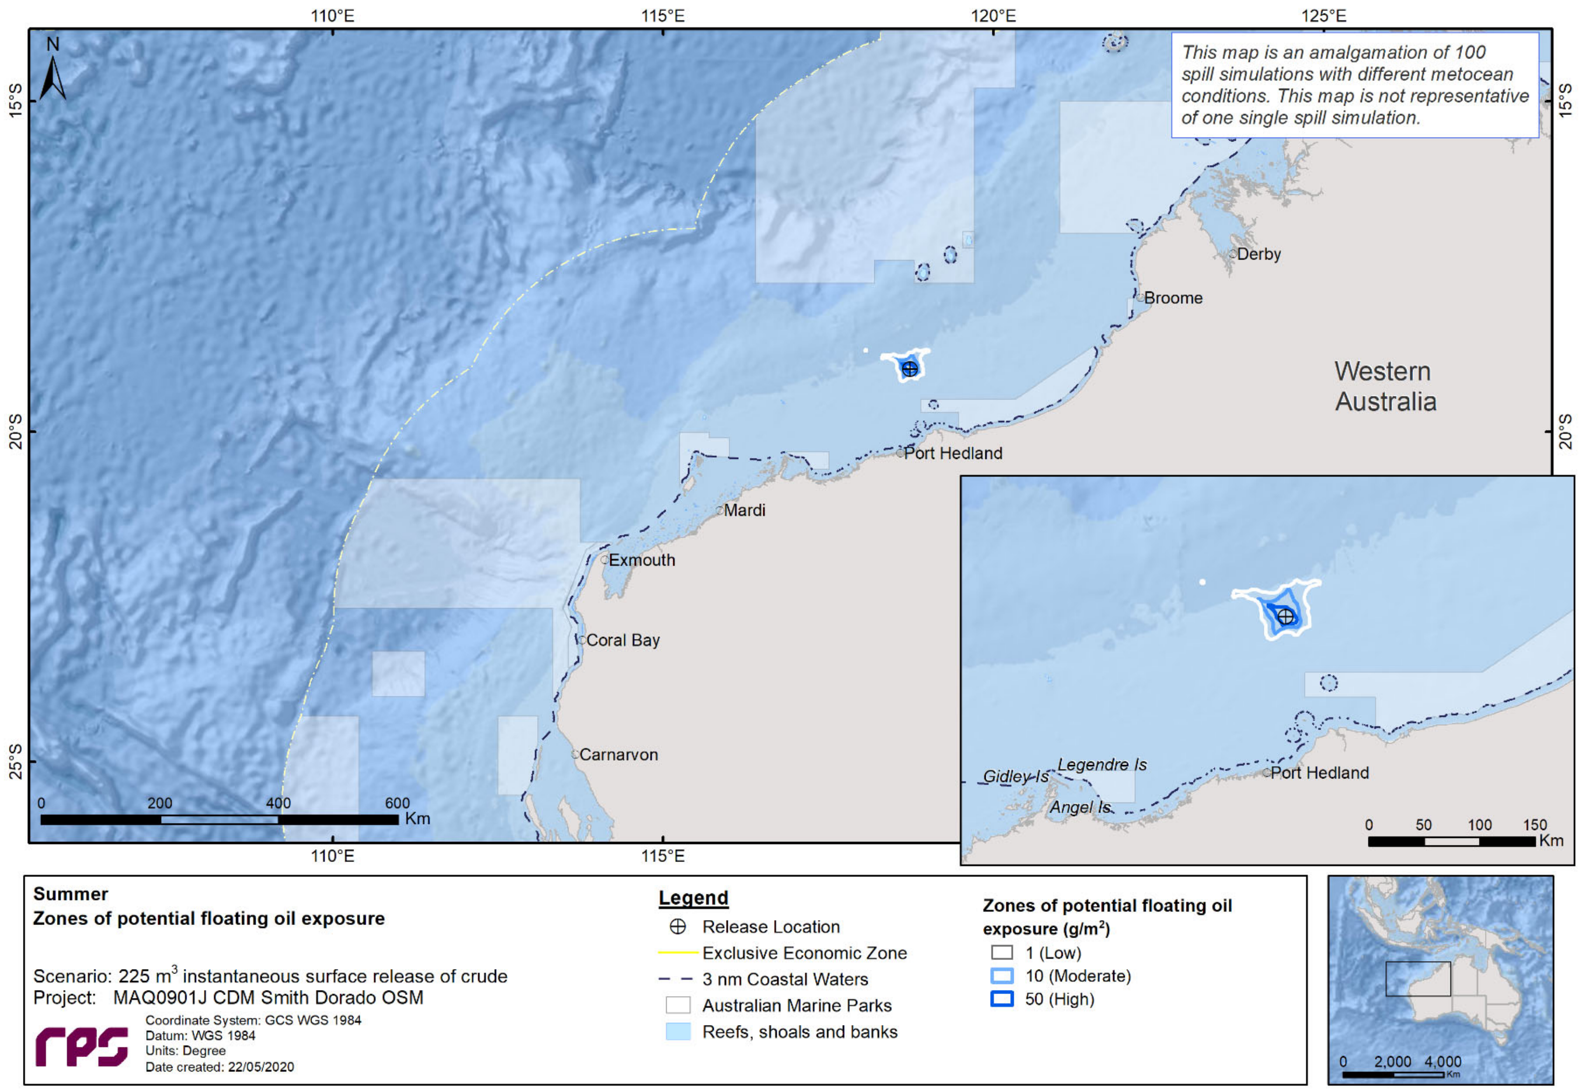

Figure 9.80 Predicted zones of potential floating oil resulting from an instantaneous surface release of 225 m^3 of crude at the FPSO. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

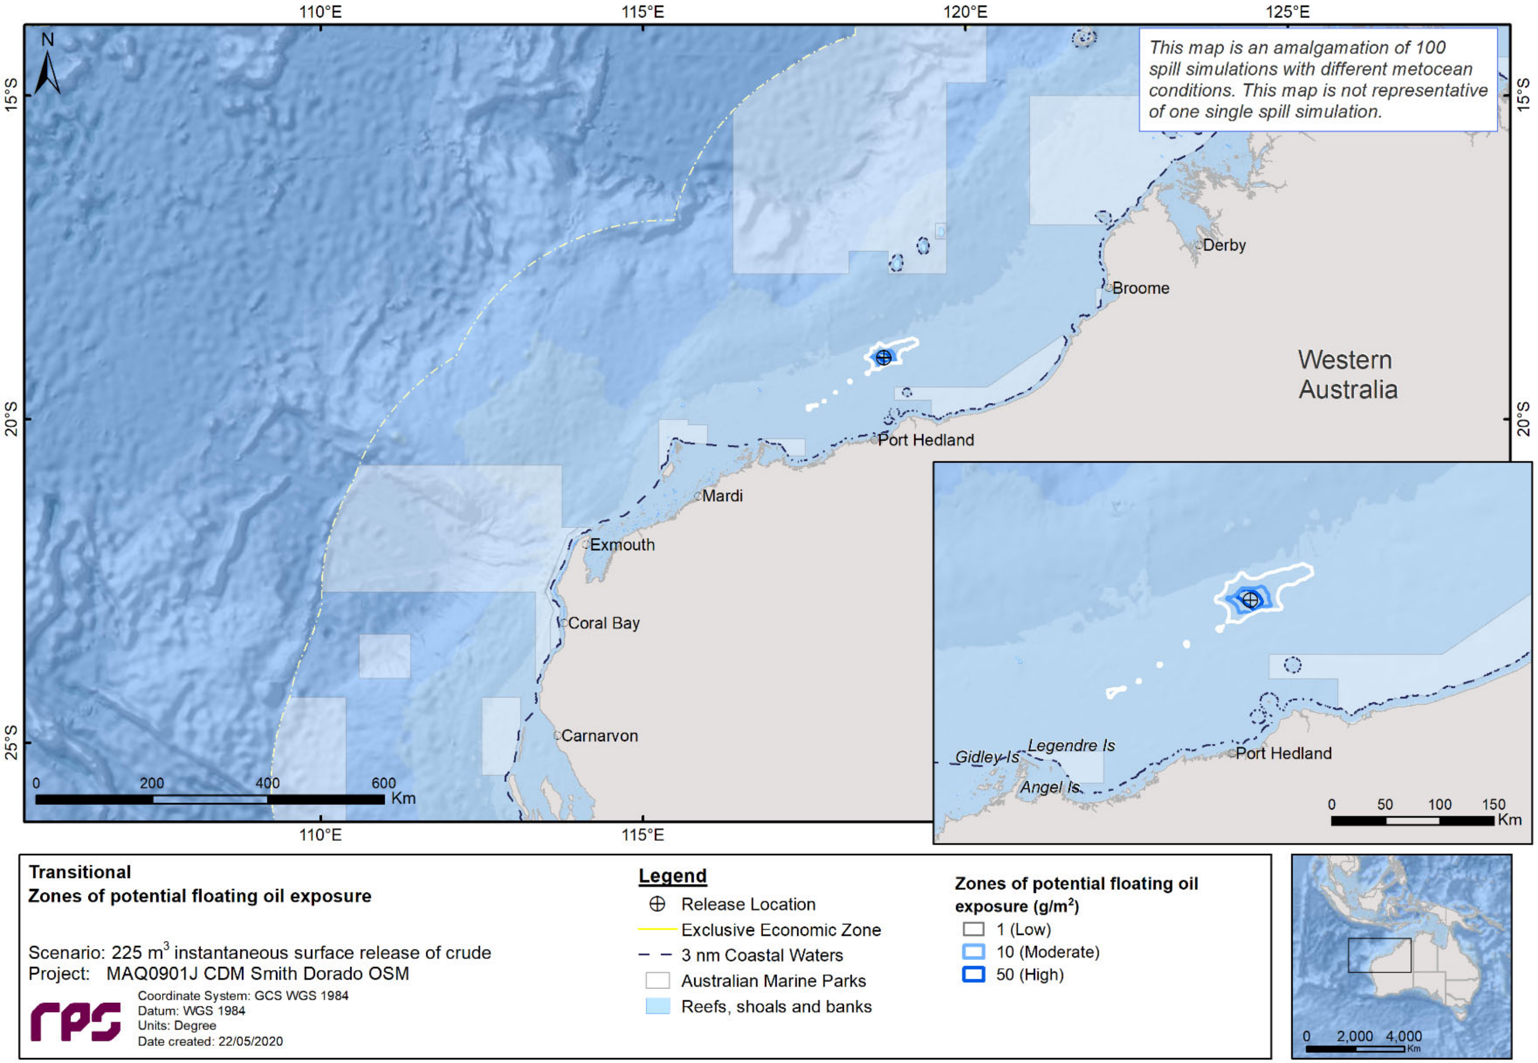

Figure 9.81 Predicted zones of potential floating oil resulting from an instantaneous surface release of 225 m^3 of crude at the FPSO. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

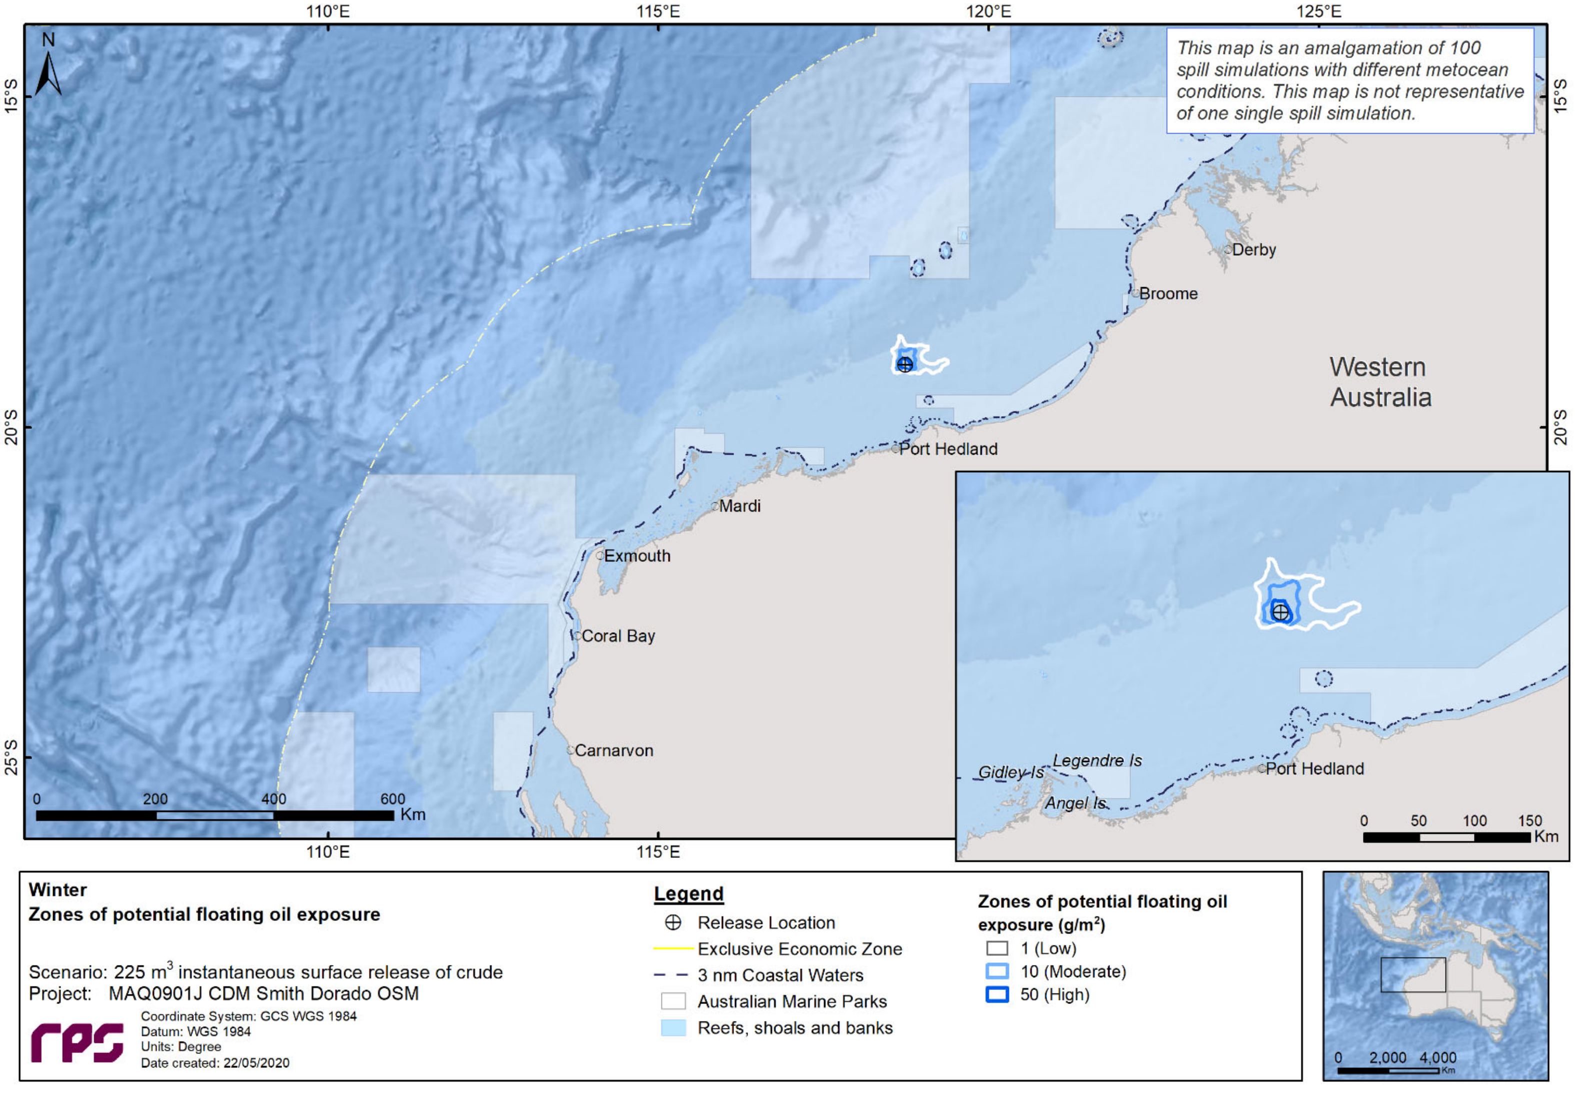

Figure 9.82 Predicted floating oil exposure zones resulting from an instantaneous surface release of 225 m^3 of crude at the FPSO. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.4.3.2 Shoreline Accumulation

There was no shoreline accumulation predicted for any spills during this scenario at or above the low threshold (≥10 g/m^2).

9.4.3.3 Entrained Hydrocarbons

Images of entrained hydrocarbon exposure in the 0-10m depth layer in Figure 9.83, Figure 9.84 and Figure 9.85 for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively. The results indicated that exposure at the low threshold was predicted to occur up to a maximum distance of 962 km (southwest) from the spill site during transitional conditions. This distance reduced to 237 km (west-southwest) as the threshold increased to moderate in transitional conditions. The maximum distances for summer and winter conditions at the low threshold were 591 km and 461 m, respectively. The maximum distances at the moderate threshold were reduced to 157 km for summer and 98 km for winter conditions.

Table 9.32 to Table 9.34 summarise the probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer for each season. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at their shallowest depth from the sea surface.

A total of 5 AMPs are within the low exposure zone for the summer and transitional results and the probability of exposure was between 1 – 2%. The shortest time for entrained hydrocarbons to reach an AMP at the low threshold was recorded at Dampier during transitional conditions as 0.96 days (23 hours).

No KEF receptors were predicted to be exposed by entrained hydrocarbons at the low threshold.

Rankin Bank was the only RSB predicted to be exposed by entrained hydrocarbons at the low threshold during transitional (2%) and winter (1%) conditions, while Imperieuse Reef was the only receptor exposed during summer conditions (1%). The quickest time before exposure at the low threshold was predicted at Rankin Bank (5.58 days) during transitional conditions.

Entrained hydrocarbons at the low threshold were predicted to cross into WA State Waters during summer and transitional conditions with probabilities of only 1%. The minimum time before oil crossed the WA State Waters boundary was 2.42 days, for a spill commencing during transitional conditions.

Table 9.32 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer. Results are based on an instantaneous surface release of 225 m³ of crude at the FPSO during summer (October to March) conditions. The results were calculated from 100 spill simulations.

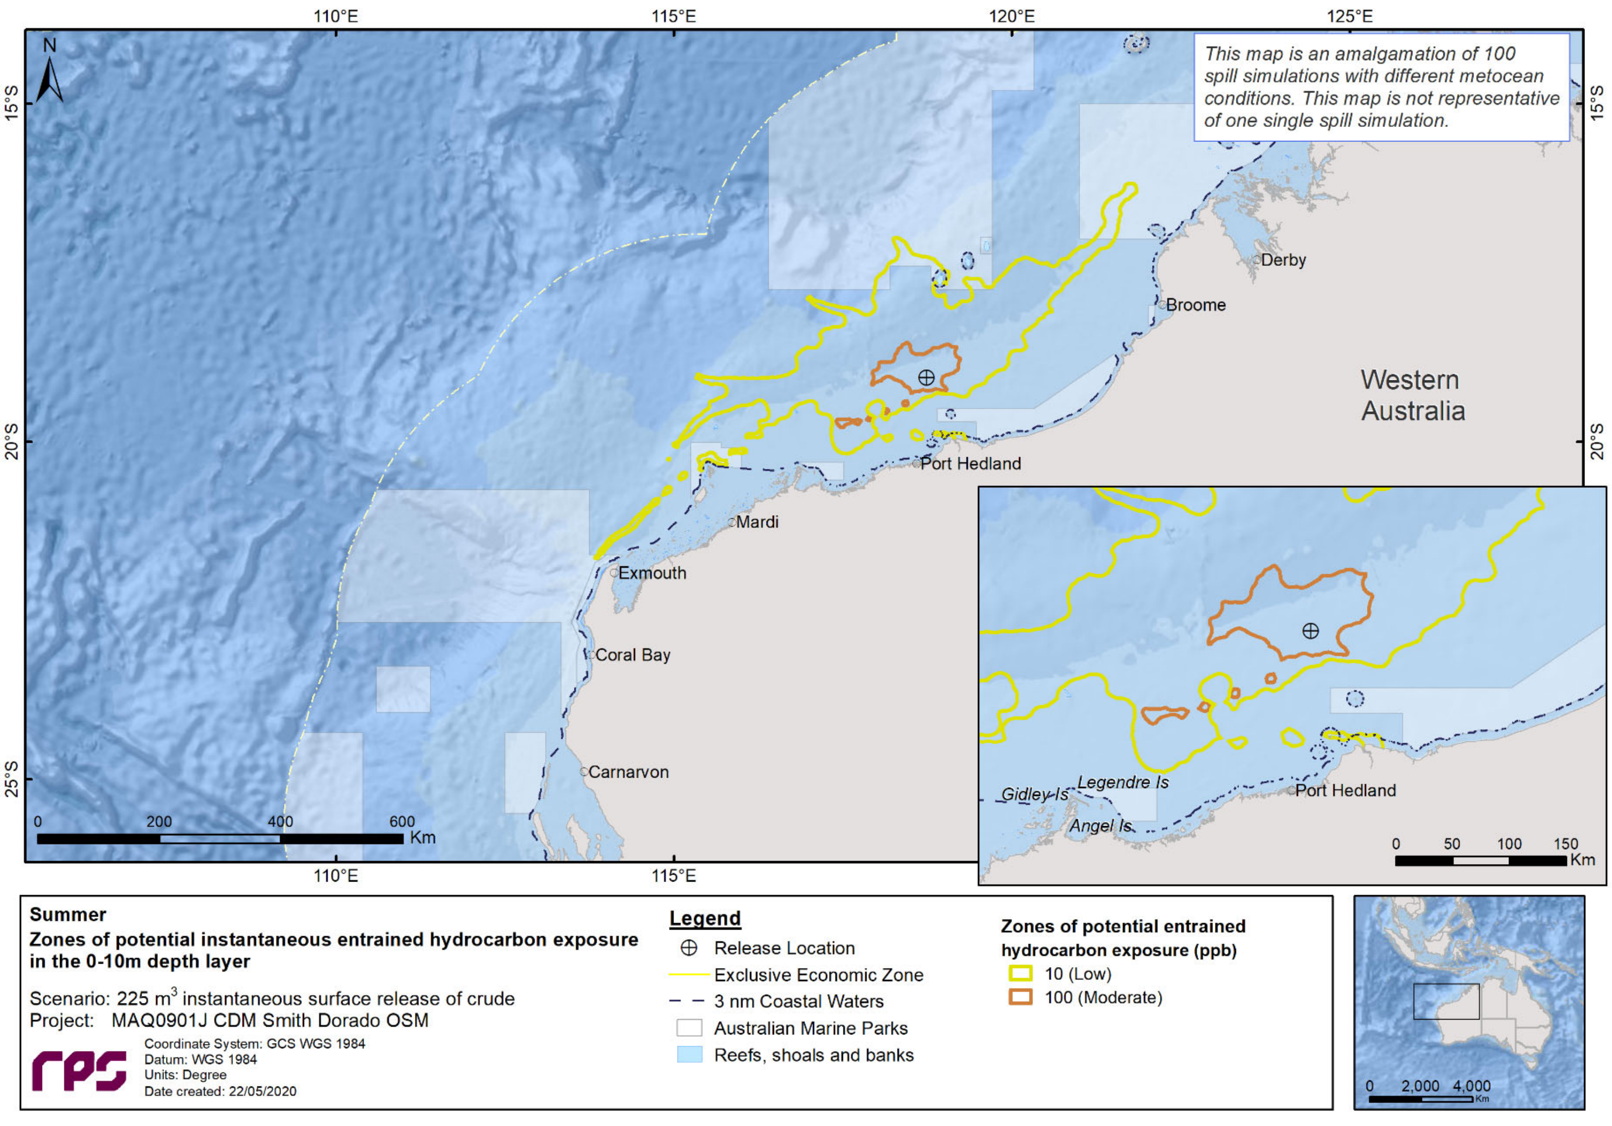

Figure 9.83 Predicted entrained hydrocarbon exposure zones resulting from an instantaneous surface release of 225 m³ of crude at the FPSO. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

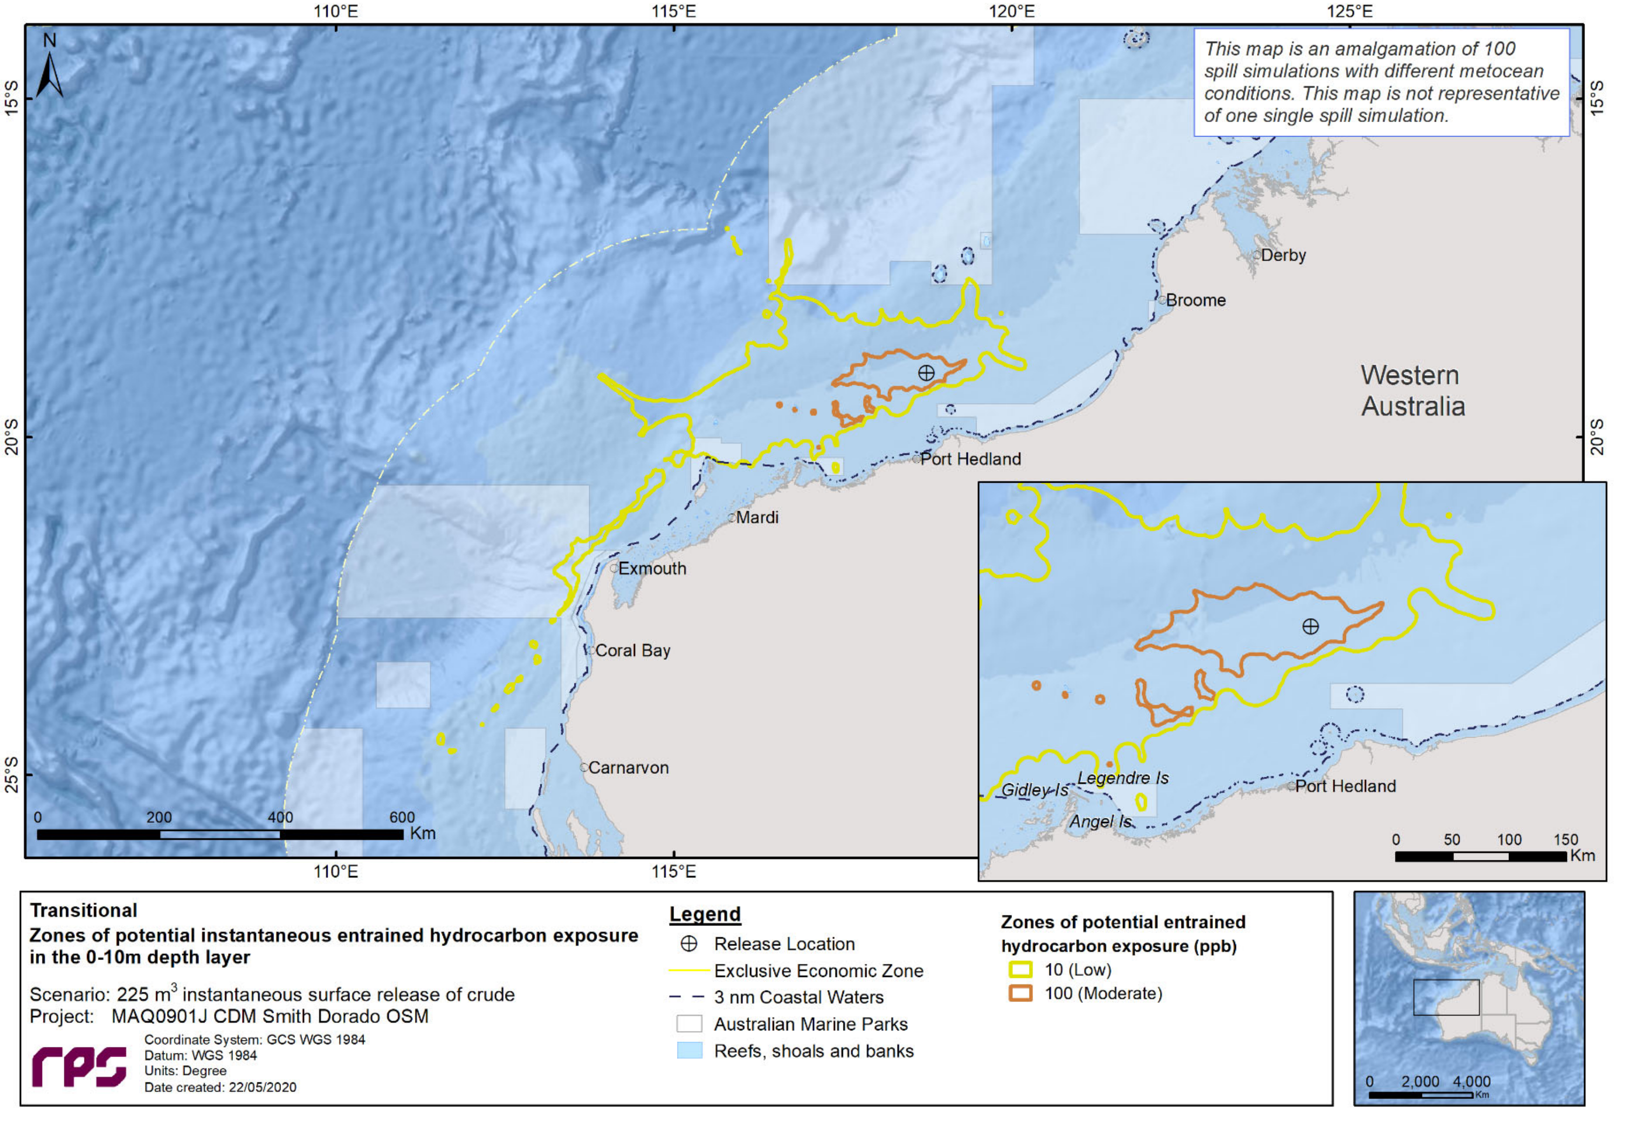

Figure 9.84 Predicted entrained hydrocarbon exposure zones resulting from an instantaneous surface release of 225 m³ of crude at the FPSO. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

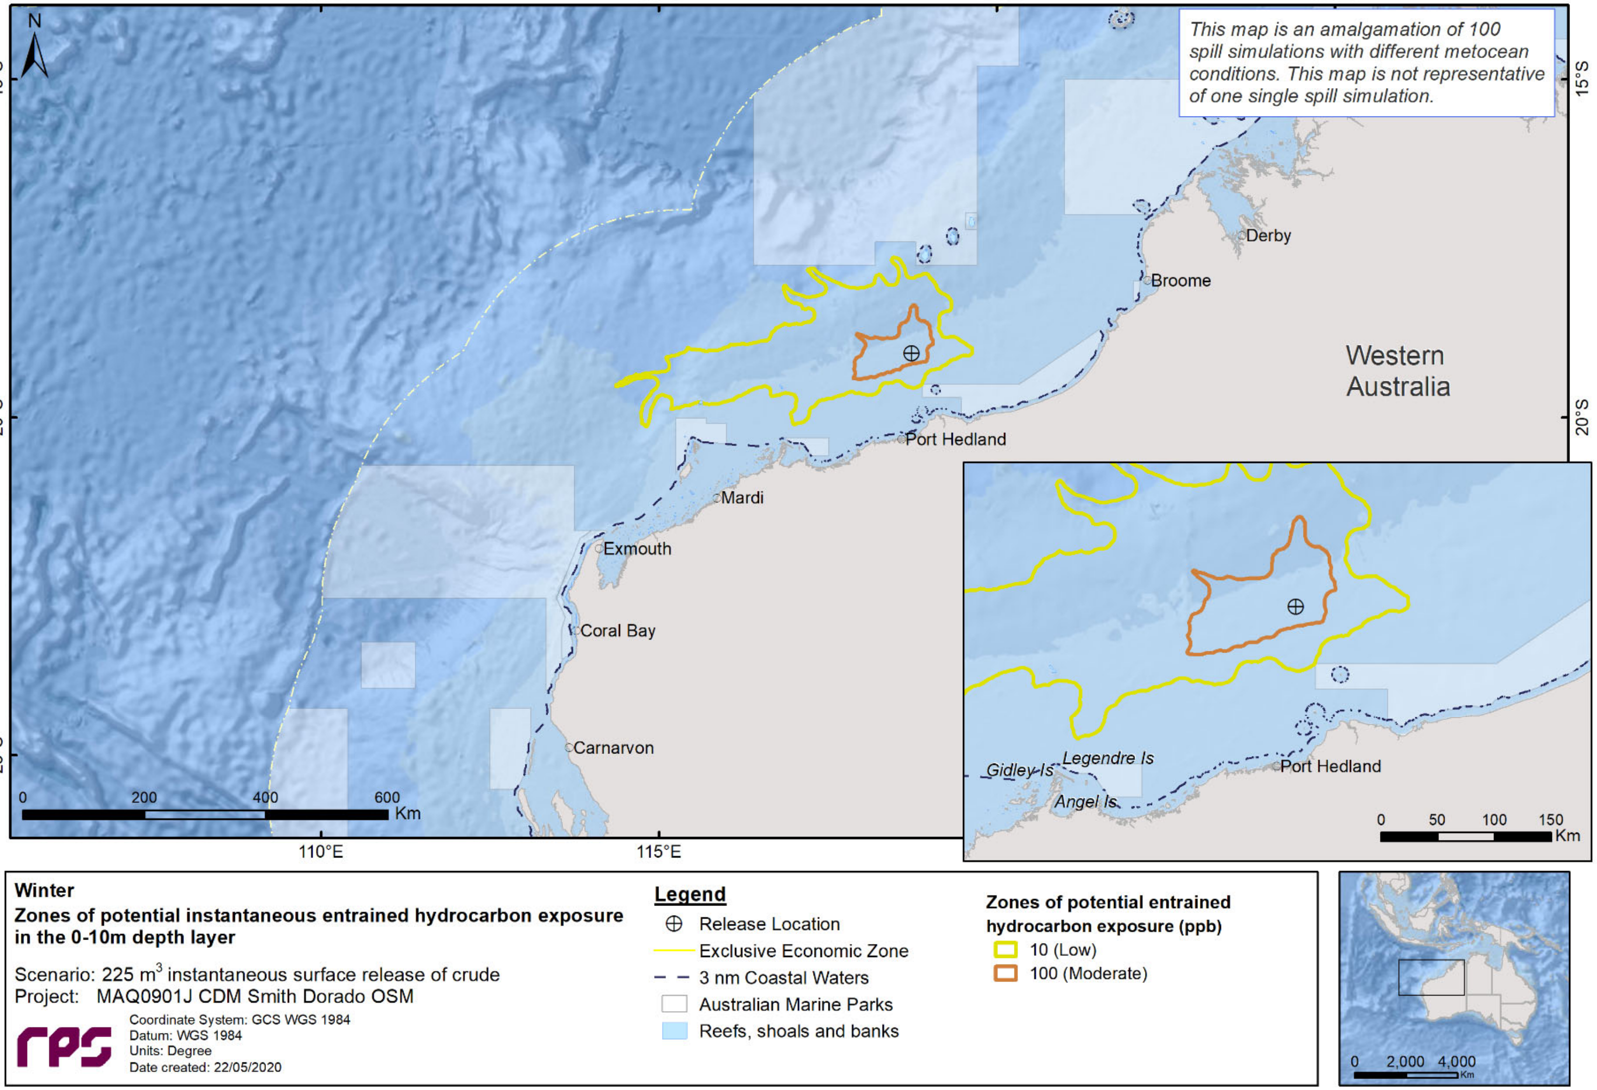

Figure 9.85 Predicted entrained hydrocarbon exposure zones resulting from an instantaneous surface release of 225 m³ of crude at the FPSO. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.4.3.4 Dissolved Hydrocarbons

Images of dissolved hydrocarbon exposure zones are depicted in Figure 9.86, Figure 9.87 and Figure 9.88 for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively. The results indicated that the low threshold (10-50 ppb) was predicted to occur up to a maximum distance of 381 km (northeast) from the release location during summer conditions. The maximum distances for transitional and winter conditions at the low threshold were 346 km and 259 m, respectively. No exposure at the moderate (50-400 ppb) or high (≥ 400 ppb) thresholds was predicted in any of the seasons assessed.

Table 9.35 to Table 9.37 summarise the probability of exposure to receptors from instantaneous dissolved hydrocarbons in the 0-10 m depth layer, across all seasonal conditions. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at their shallowest depth from the sea surface.

The Argo-Rowley Terrace AMP was the only AMP to be exposed to dissolved hydrocarbons at the low threshold, with a probability of 1% predicted in summer conditions with a minimum time of 8.17 days before exposure.

No KEF or RSB receptors were predicted to be exposed by dissolved hydrocarbons at the low threshold.

Dissolved hydrocarbons at the low threshold were predicted to cross into WA State Waters during the transitional season with a probability of 1%, after 2.33 days.

Table 9.35 Probability of exposure to individual receptors from instantaneous dissolved hydrocarbons in the 0-10 m depth layer. Results are based on an instantaneous surface release of 225 m^3 of crude at the FPSO during summer (October to March) conditions. The results were calculated from 100 spill simulations.

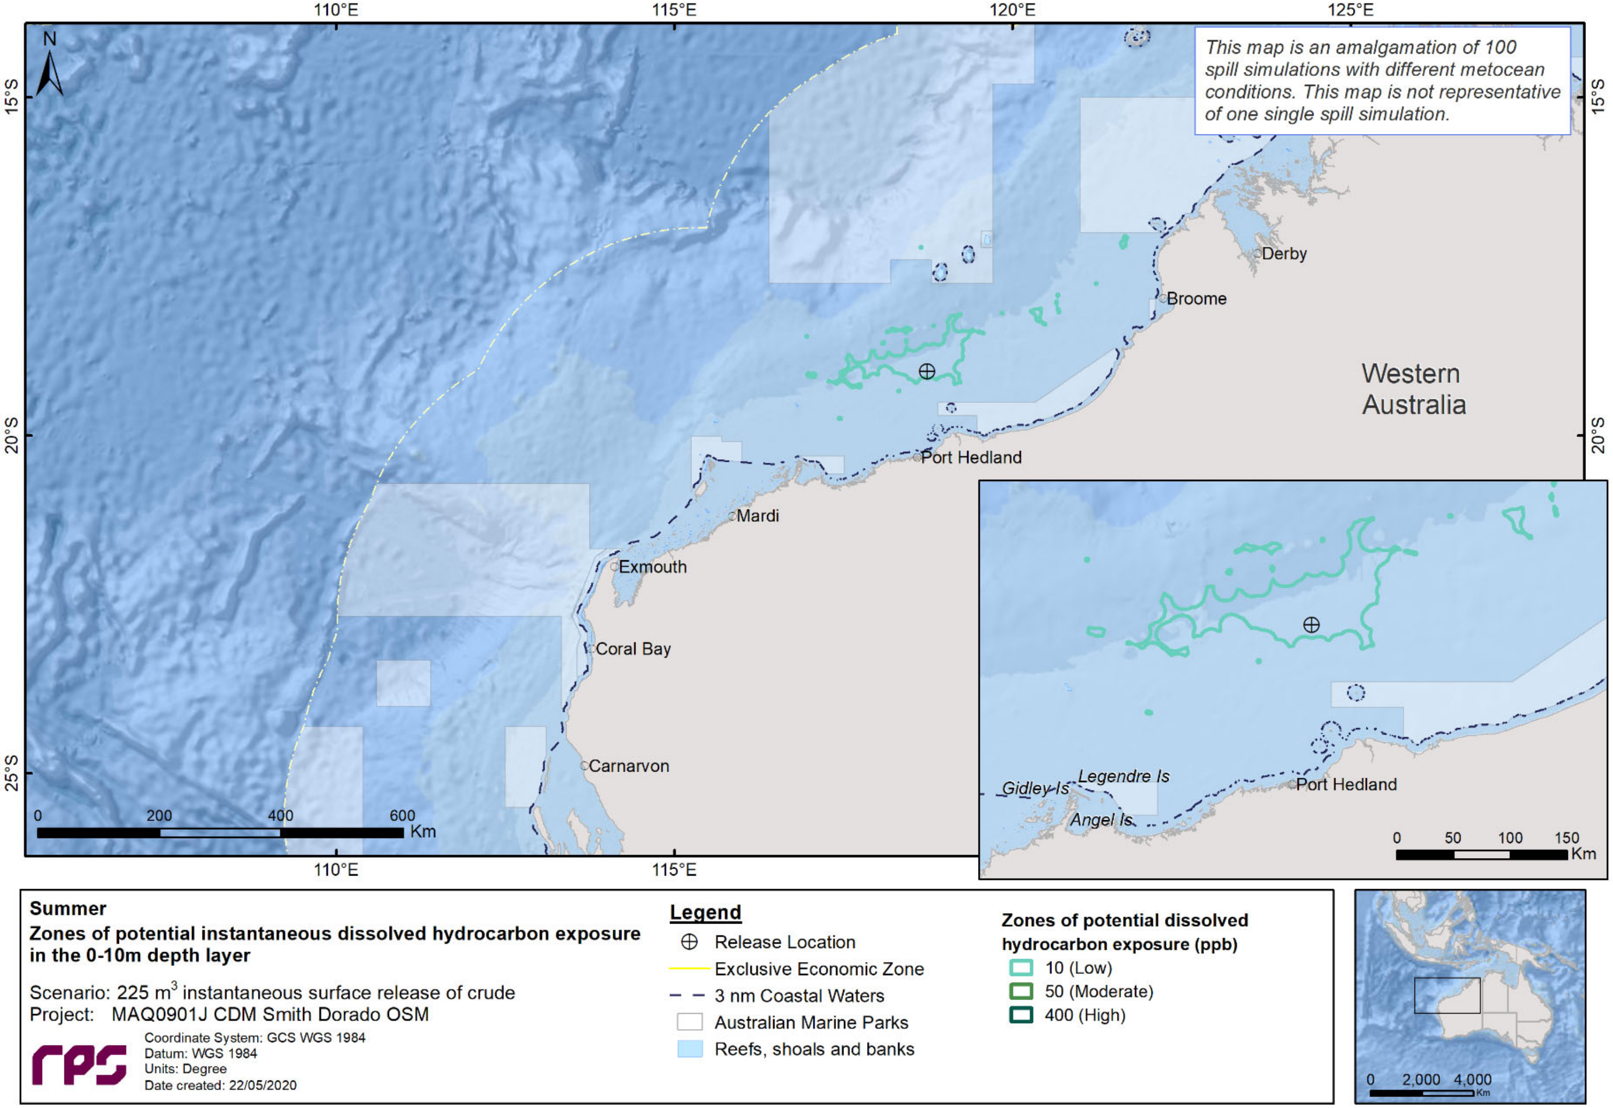

Figure 9.86 Predicted dissolved hydrocarbon exposure zones resulting from an instantaneous surface release of 225 m³ of crude at the FPSO. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

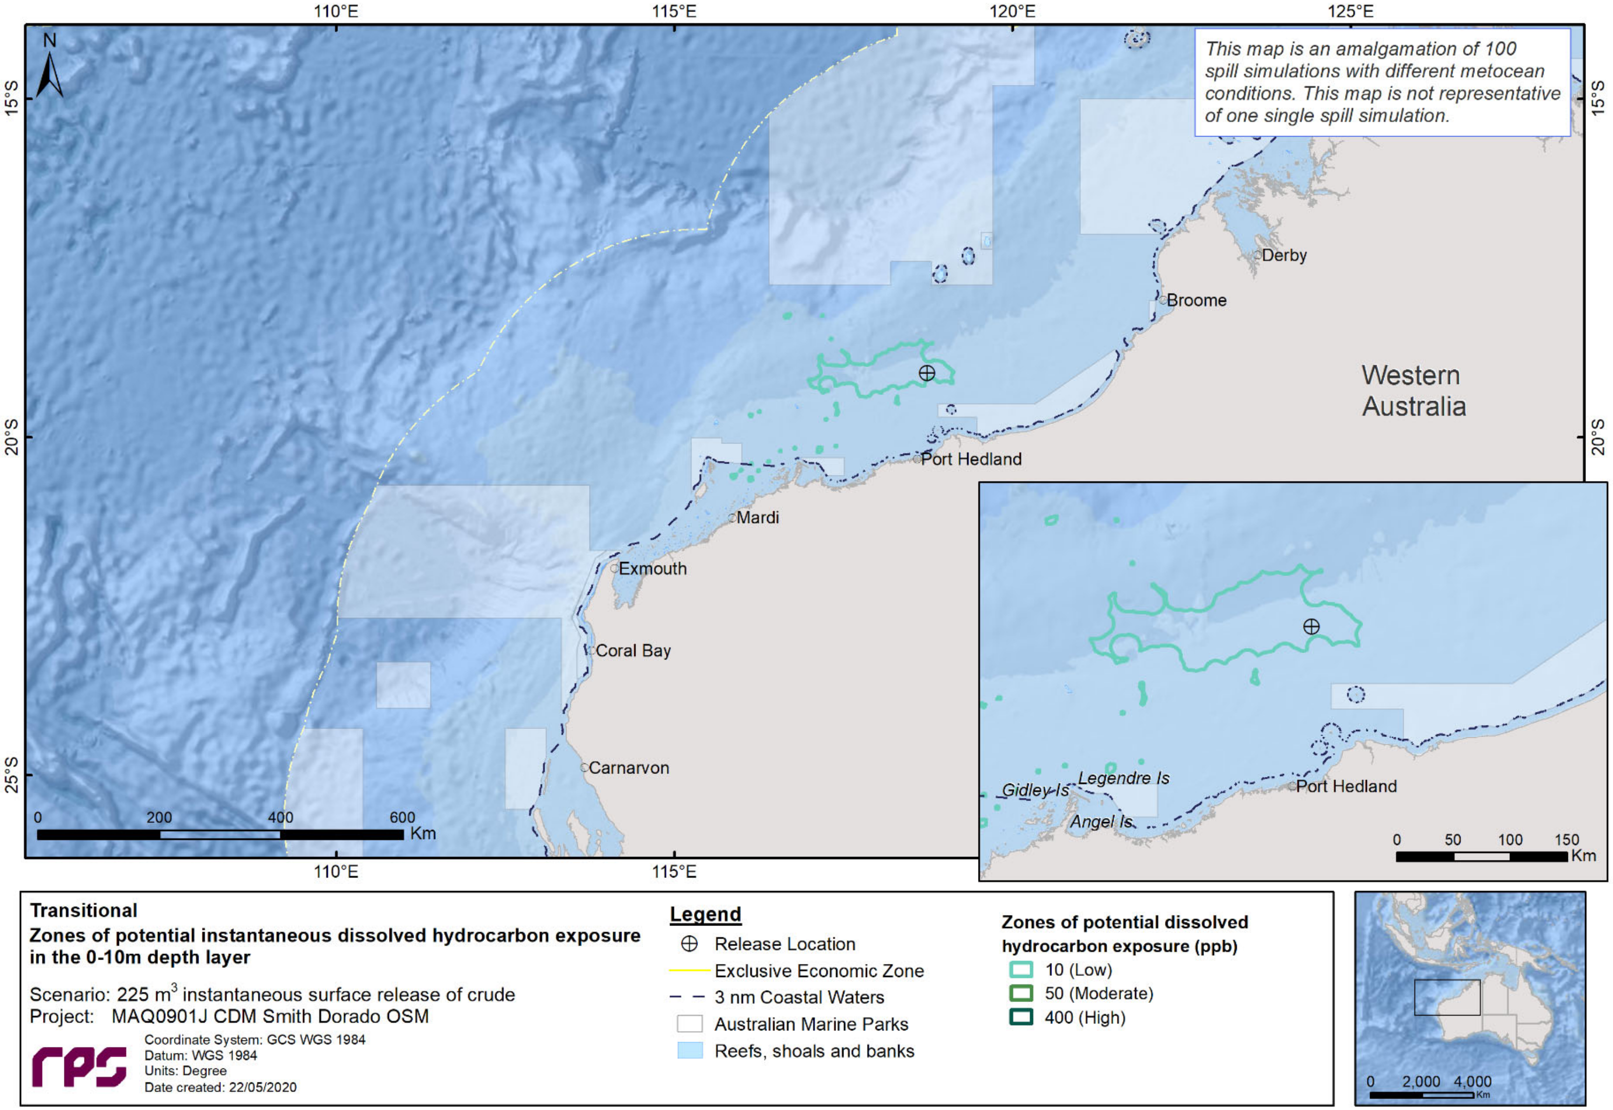

Figure 9.87 Predicted dissolved hydrocarbon exposure zones resulting from an instantaneous surface release of 225 m^3 of crude at the FPSO. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

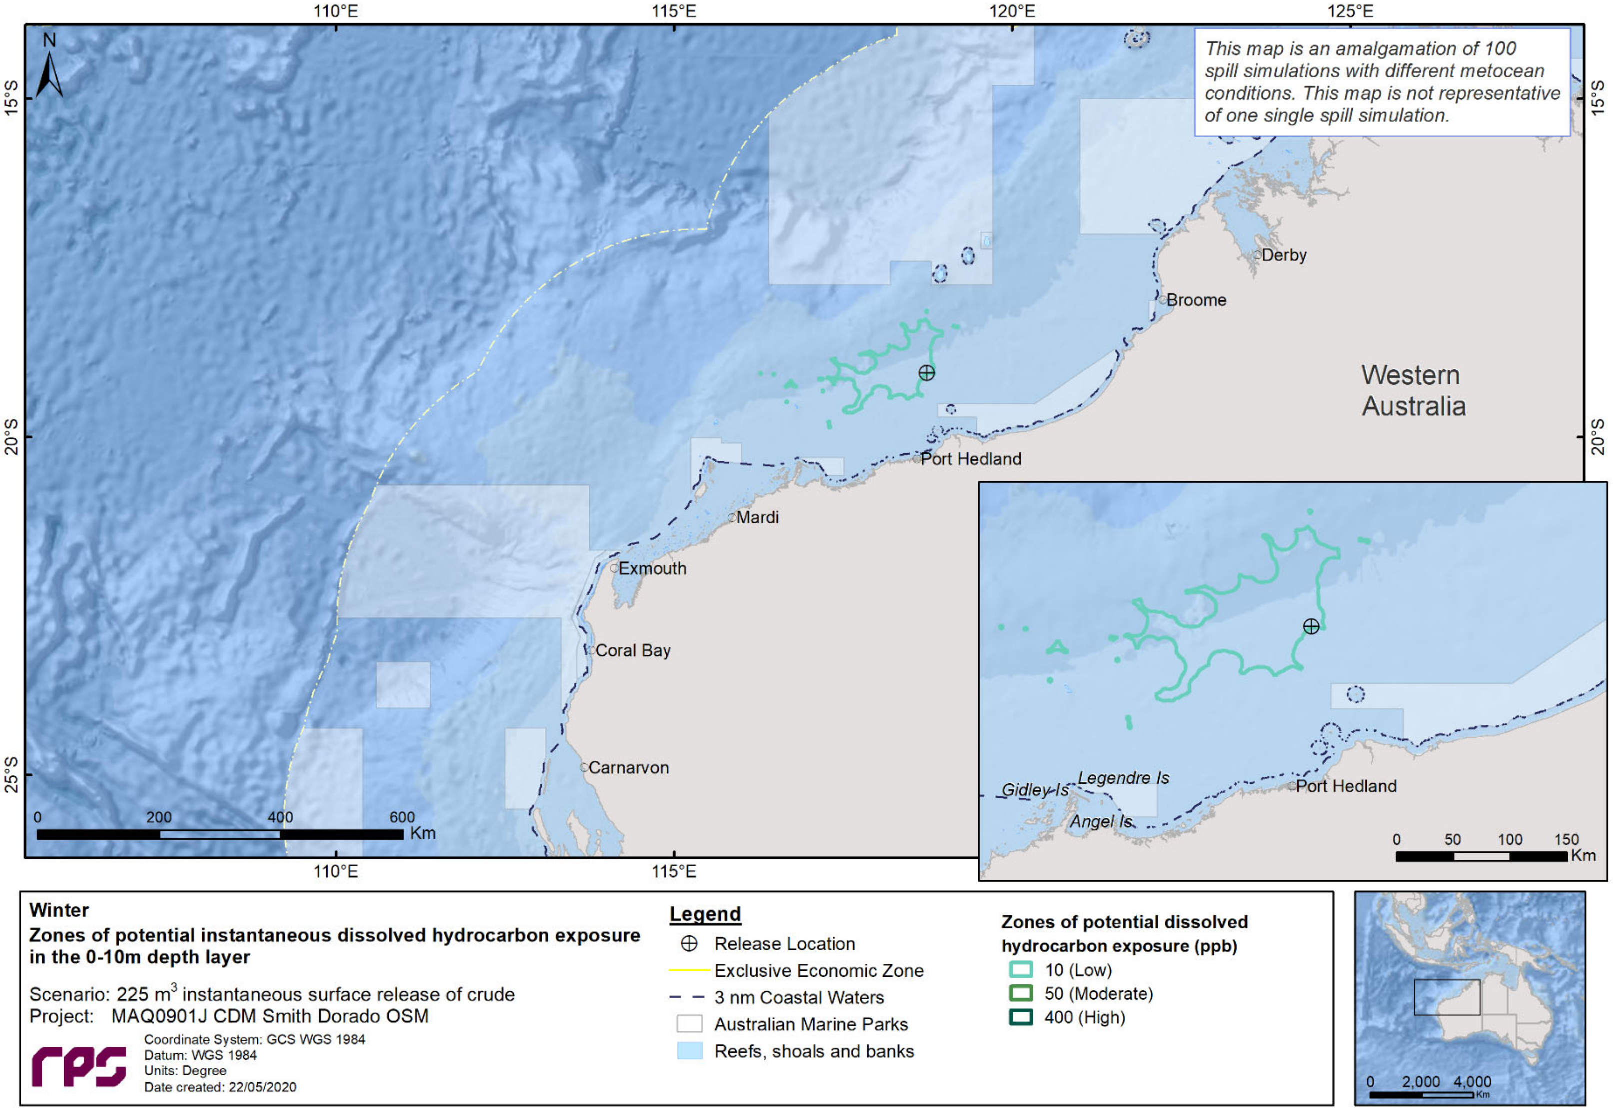

Figure 9.88 Predicted dissolved hydrocarbon exposure zones resulting from an instantaneous surface release of 225 m³ of crude at the FPSO. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.5 Scenario 5: Simulation of an instantaneous surface release of HFO due to a tanker collision with the FPSO

This scenario examined an instantaneous 1,800 m^3 surface release of HFO at the FPSO, tracked for 56 days. A total of 300 simulations were run across three seasons; summer, transitional and winter (i.e. 100 spills per season). These are then combined and presented as exposures zones for each season (cumulative of 100 simulations) for the low, moderate and high thresholds.

Section 9.5.1 presents an overview of the EMBA based on combining the 300 spill simulations and Section 9.5.3 shows the seasonal (or stochastic) analysis, while Section 9.5.2 presents the deterministic analysis results (i.e. a single spill simulation), based on largest volume ashore and longest results, based on largest volume ashore and longest length of oiled shoreline.

9.5.1 Overview

Figure 9.89 and Figure 9.90 are maps which encompass the full geographic EMBA derived by overlaying the combined results from all 300 spill simulations at both the low and moderate exposure thresholds, respectively.

Figure 9.91 and Figure 9.92 show the annualised extent of floating oil and in-water (entrained and dissolved) exposure as well as shoreline accumulation based on the low and moderate exposure thresholds, respectively, derived from combining all 300 spill simulations.

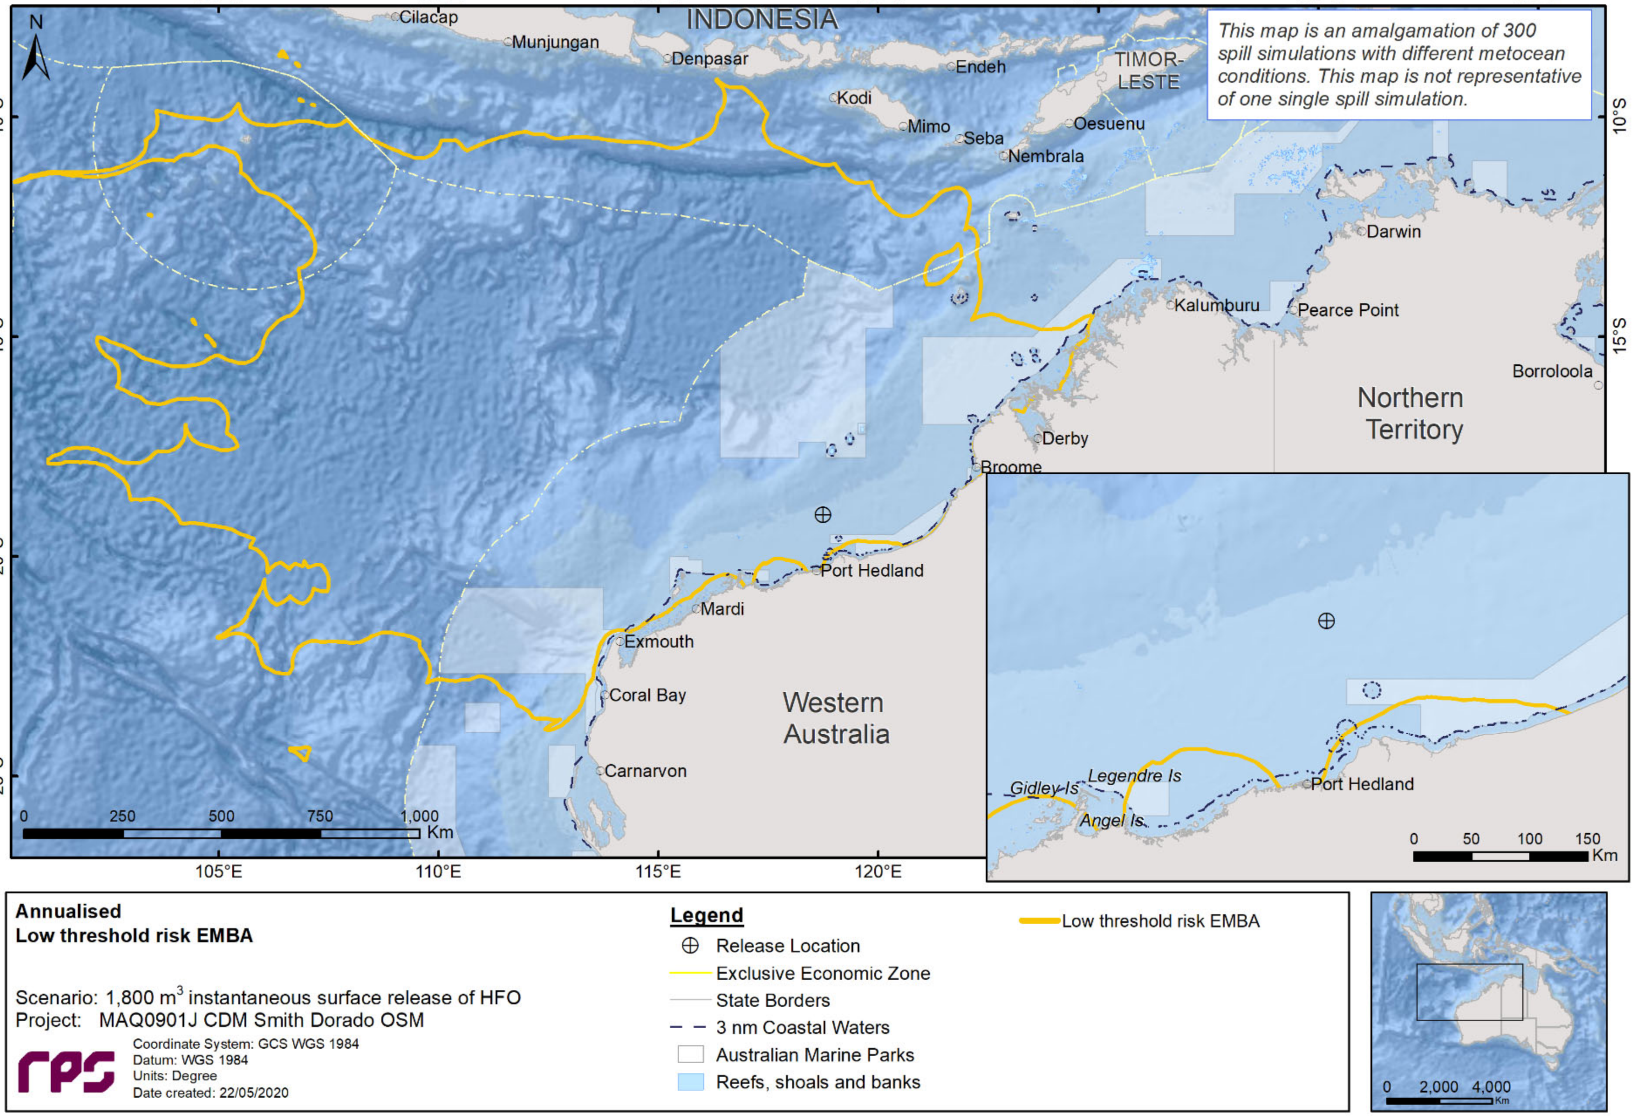

Figure 9.89 Predicted low threshold risk EMBA resulting from an instantaneous surface release of 1,800 m^3 of HFO at the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 56 days.

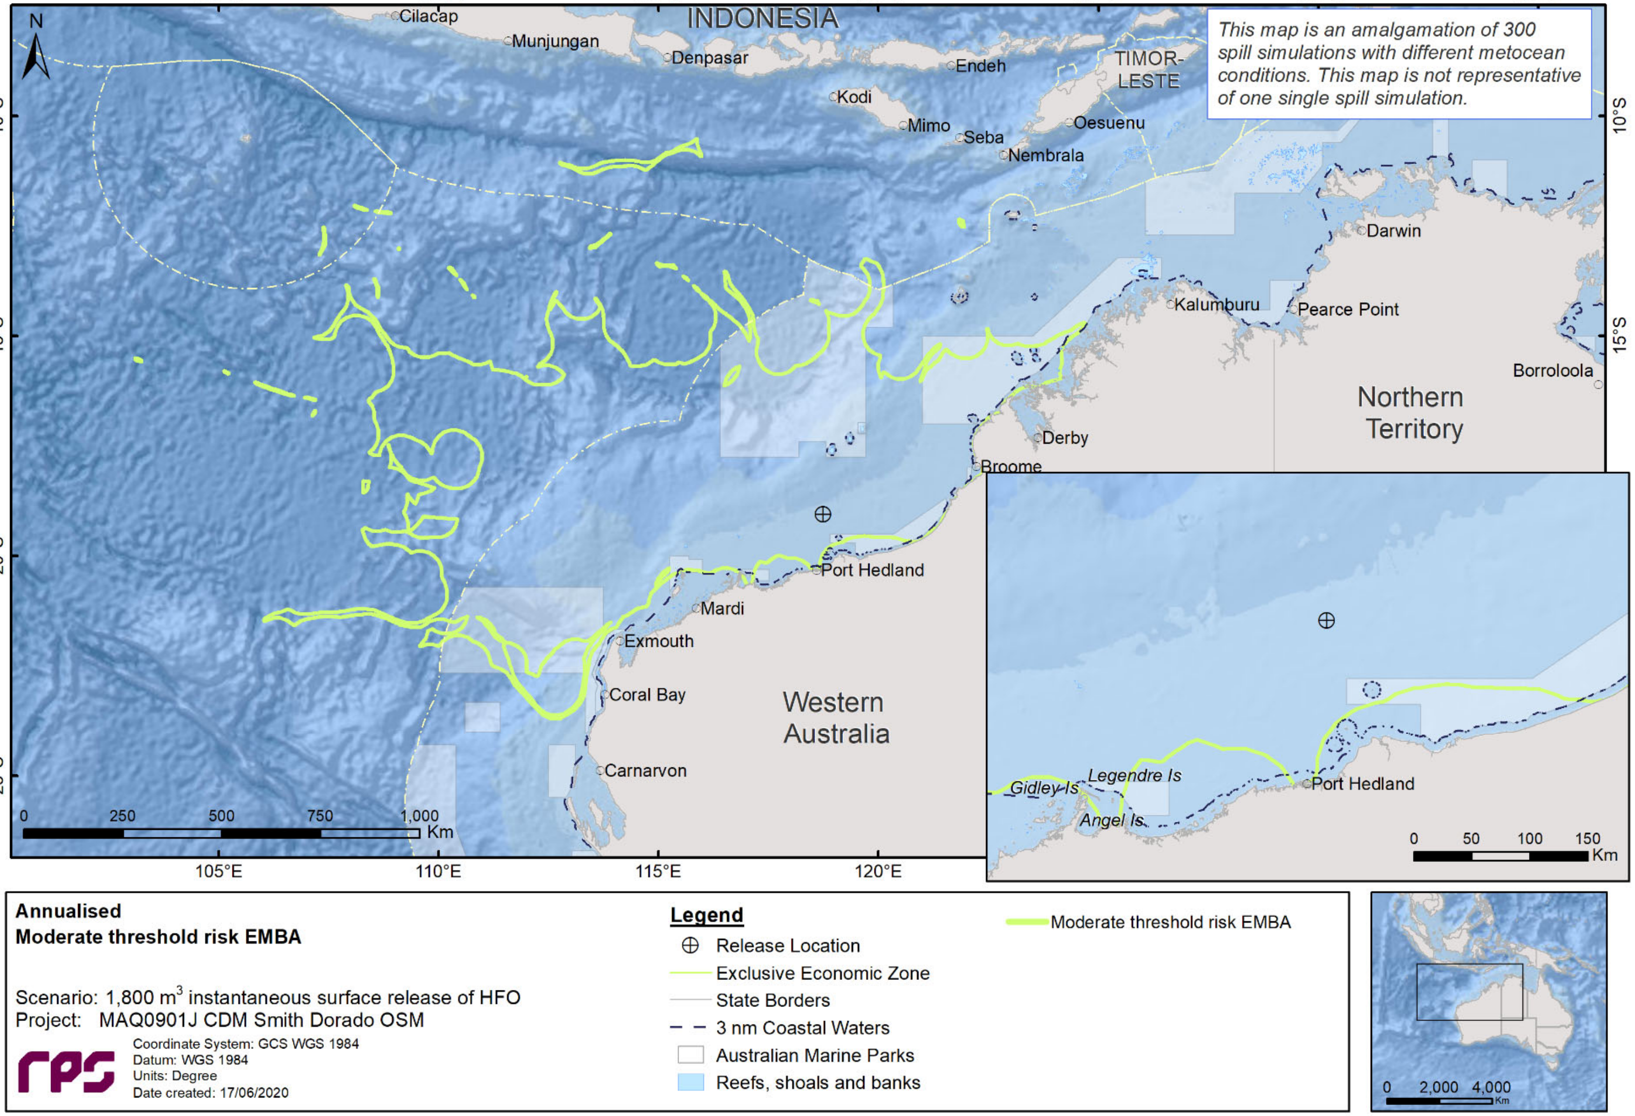

Figure 9.90 Predicted moderate threshold risk EMBA resulting from an instantaneous surface release of 1,800 m^3 of HFO at the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 56 days.

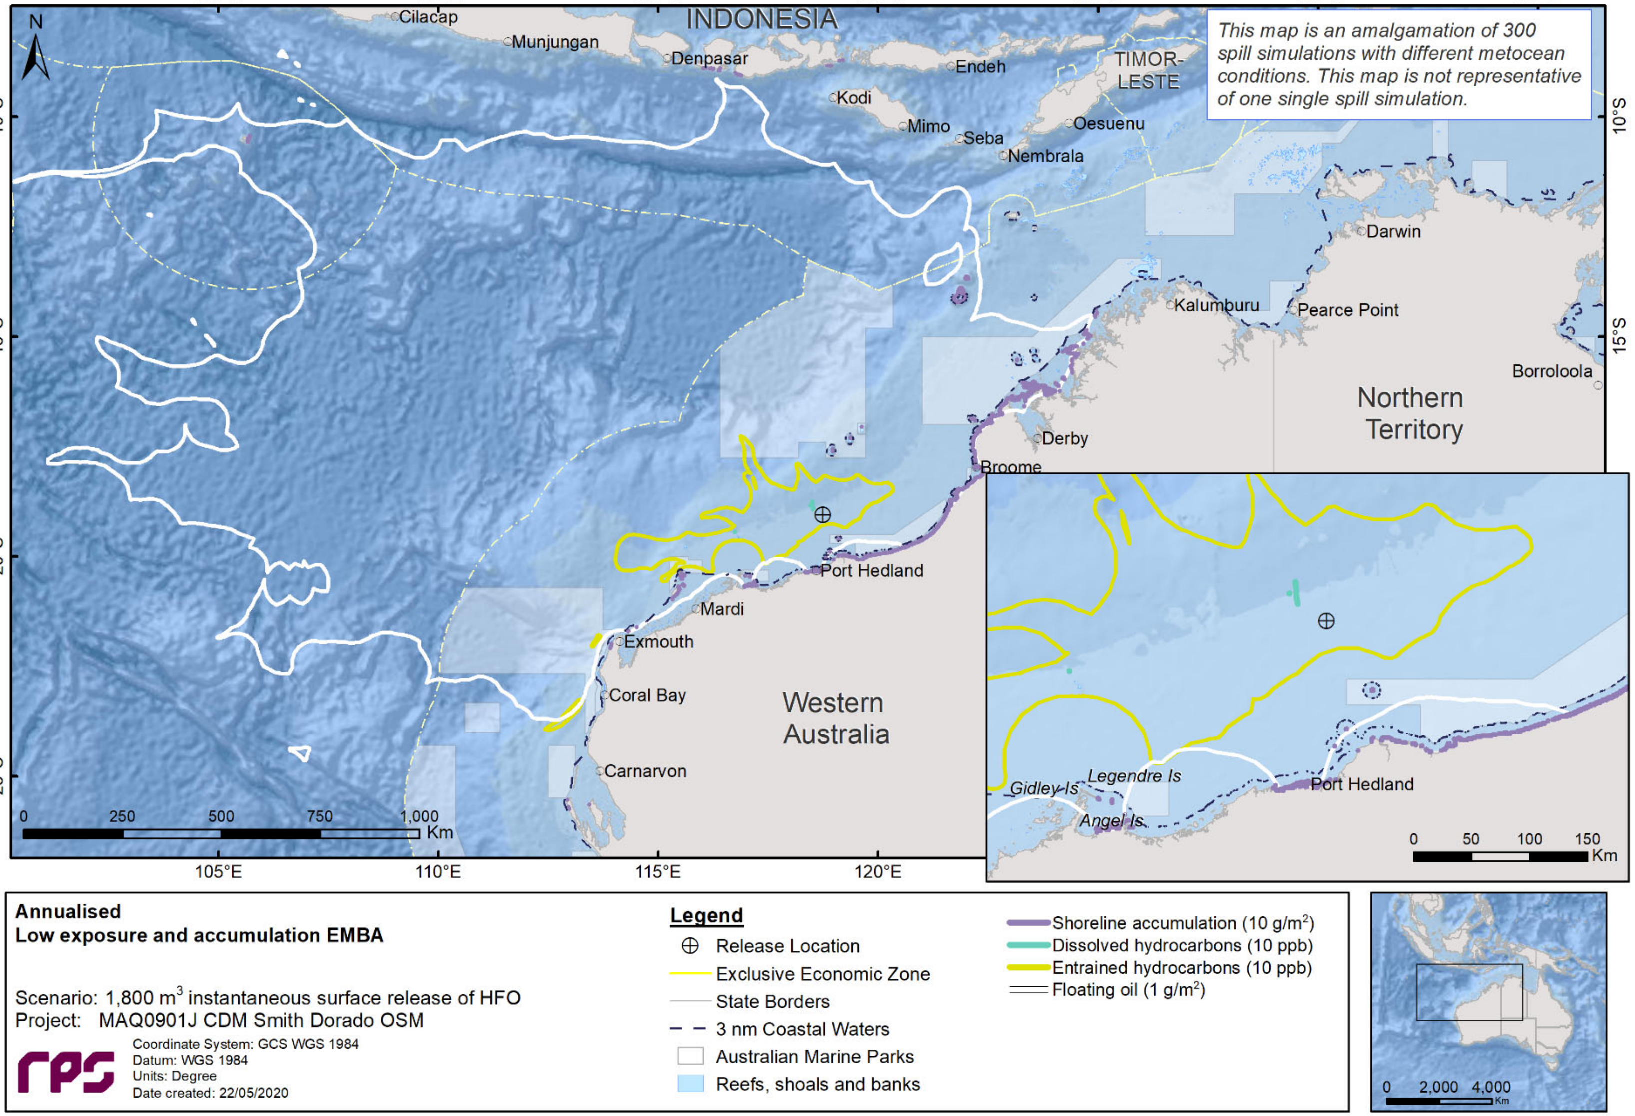

Figure 9.91 Annualised low threshold oil exposure and shoreline accumulation resulting from an instantaneous surface release of 1,800 m^3 of HFO at the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 56 days.

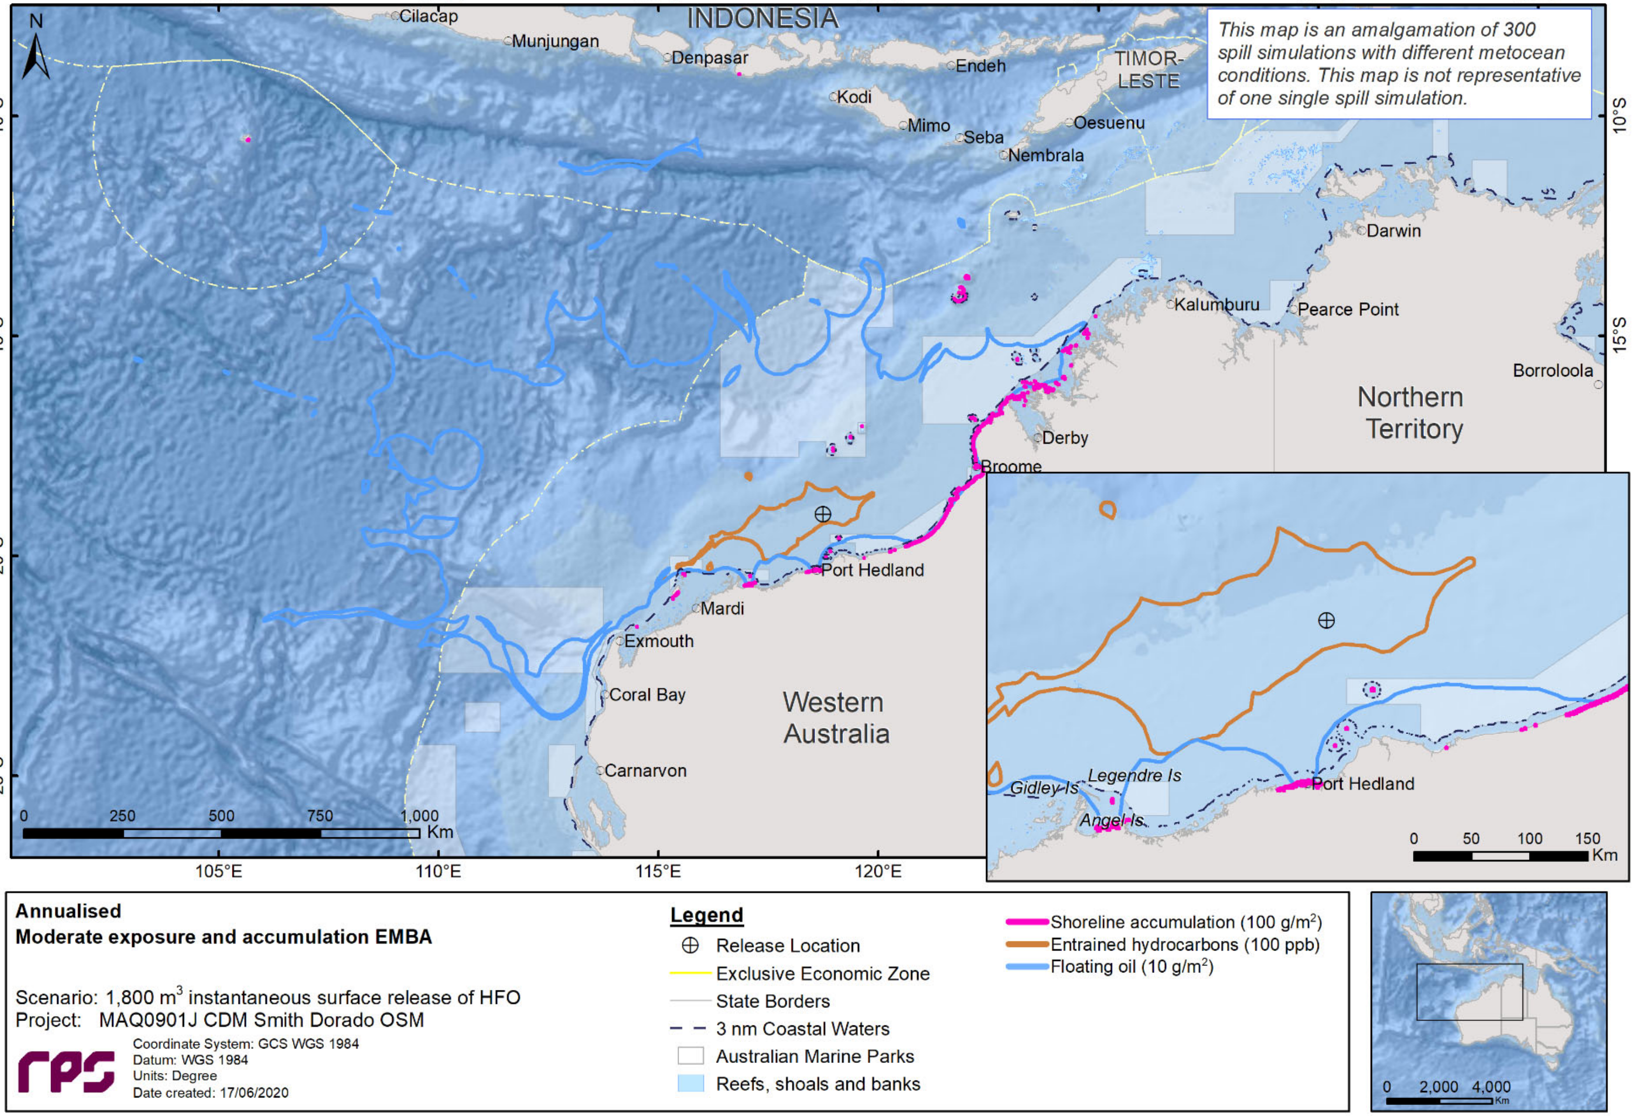

Figure 9.92 Annualised moderate threshold oil exposure and shoreline accumulation resulting from an instantaneous surface release of 1,800 m^3 of HFO at the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 56 days.

9.5.2 Deterministic Analysis

The stochastic modelling results were assessed and the deterministic runs were identified and presented below based on the following criteria;

a. Largest volume of oil ashore; and

b. Longest length of oil shoreline.

9.5.2.1 Deterministic Case: Largest volume of oil ashore

The deterministic simulation that recorded the largest volume of oil ashore was identified during summer conditions as run number 86 which commenced at 8 am on the 19th of December 2015. The maximum volume ashore was 1,684 m^3, which occurred 16 days after the initial release.

Exposure from floating oil (swept area) and potential shoreline accumulation over the entire 56 day simulation are presented in Figure 9.93 and Figure 9.94. Floating oil exposure was predicted to the northeast from the release location with oil accumulation occurring on the Broome shoreline.

Figure 9.95 the time series of the area and length of visible oil (≥1 g/m^2) and actionable floating oil exposure on the sea surface (≥50 g/m^2) and actionable shoreline oil (≥100 g/m^2) over the 56-day simulation.

Figure 9.96 is a time series of the volume on shore at the low (10-100 g/m^2), moderate (100-1,000 g/m^2) and high (≥ 1,000 g/m^2) thresholds.

Figure 9.97 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 215 m^3 (12%) spilled oil was lost to the atmosphere through evaporation. Approximately 664 m^3 (37%) of the HFO was predicted to have decayed, while 0.1 m^3 (<0.1%) remained within the water column and 921 m^3 (51%) was predicted to remain on the shoreline.

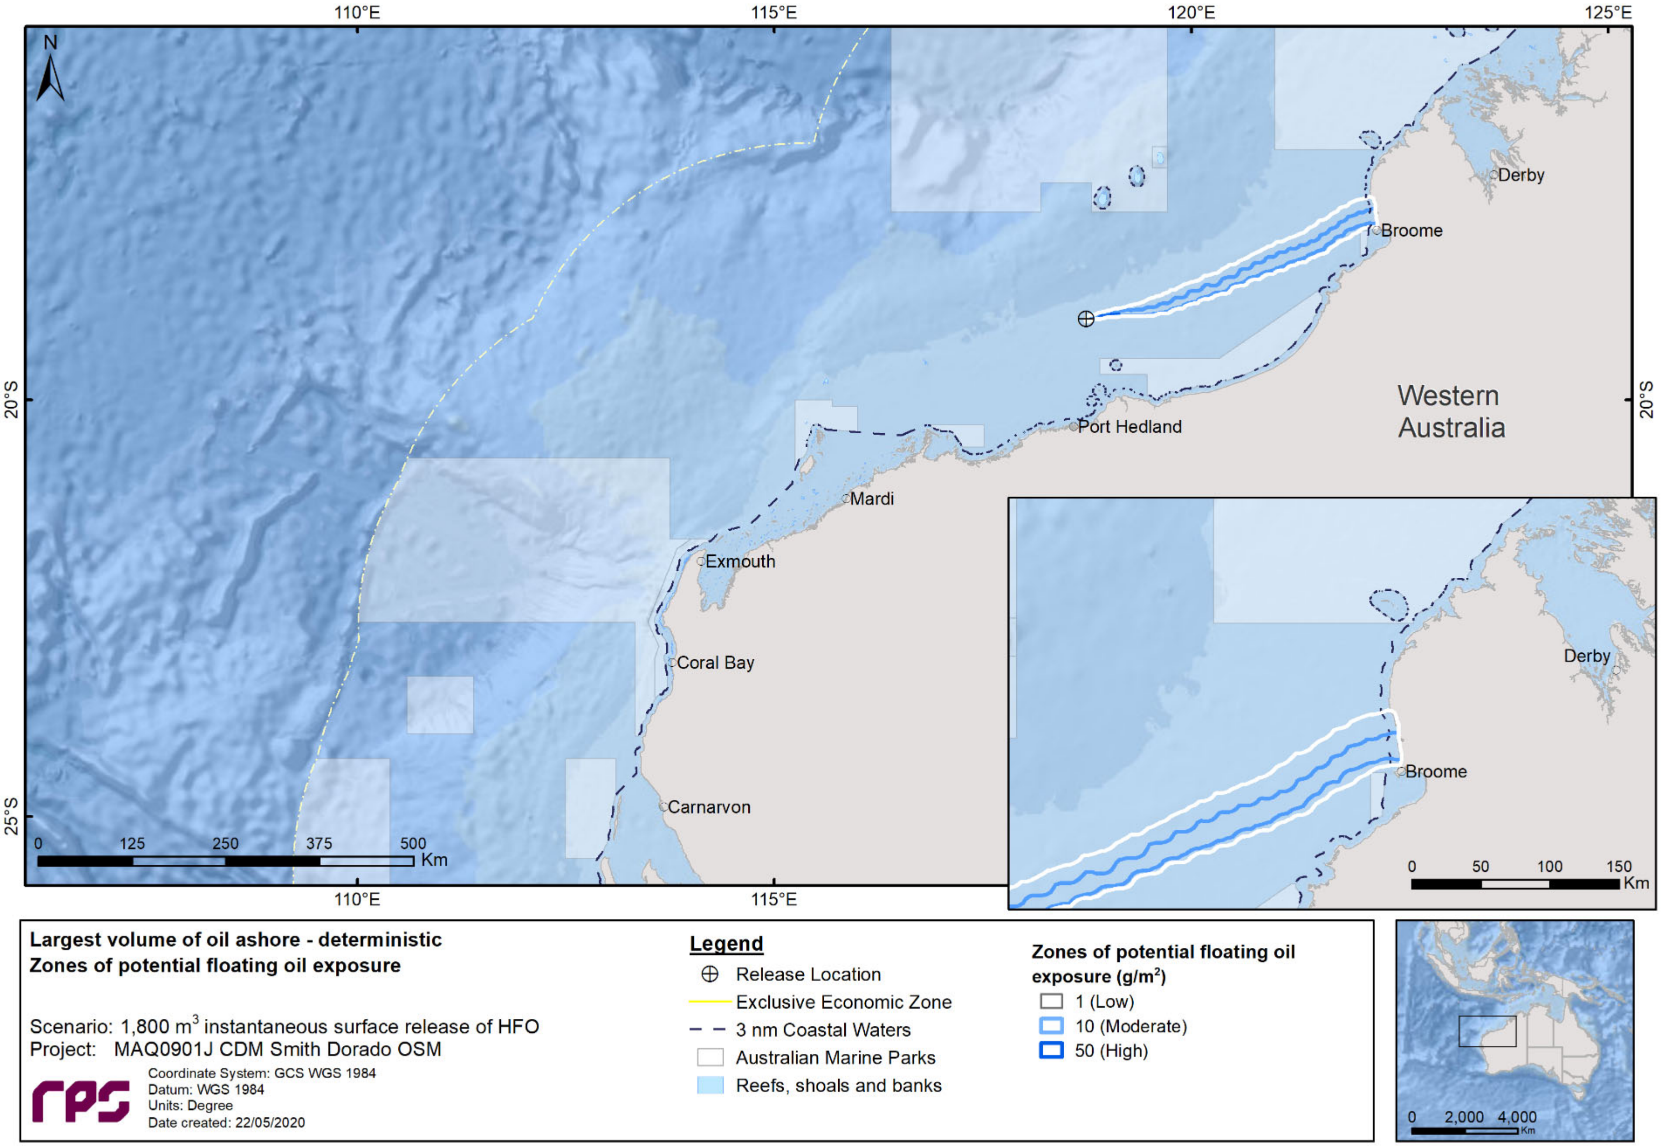

Figure 9.93 Exposure from floating oil (over the 56 day simulation) for the simulation with the largest volume of oil ashore. Results are based on an instantaneous surface release of 1,800 m^3 of HFO at the FPSO, starting 8 am on the 19th of December 2015.

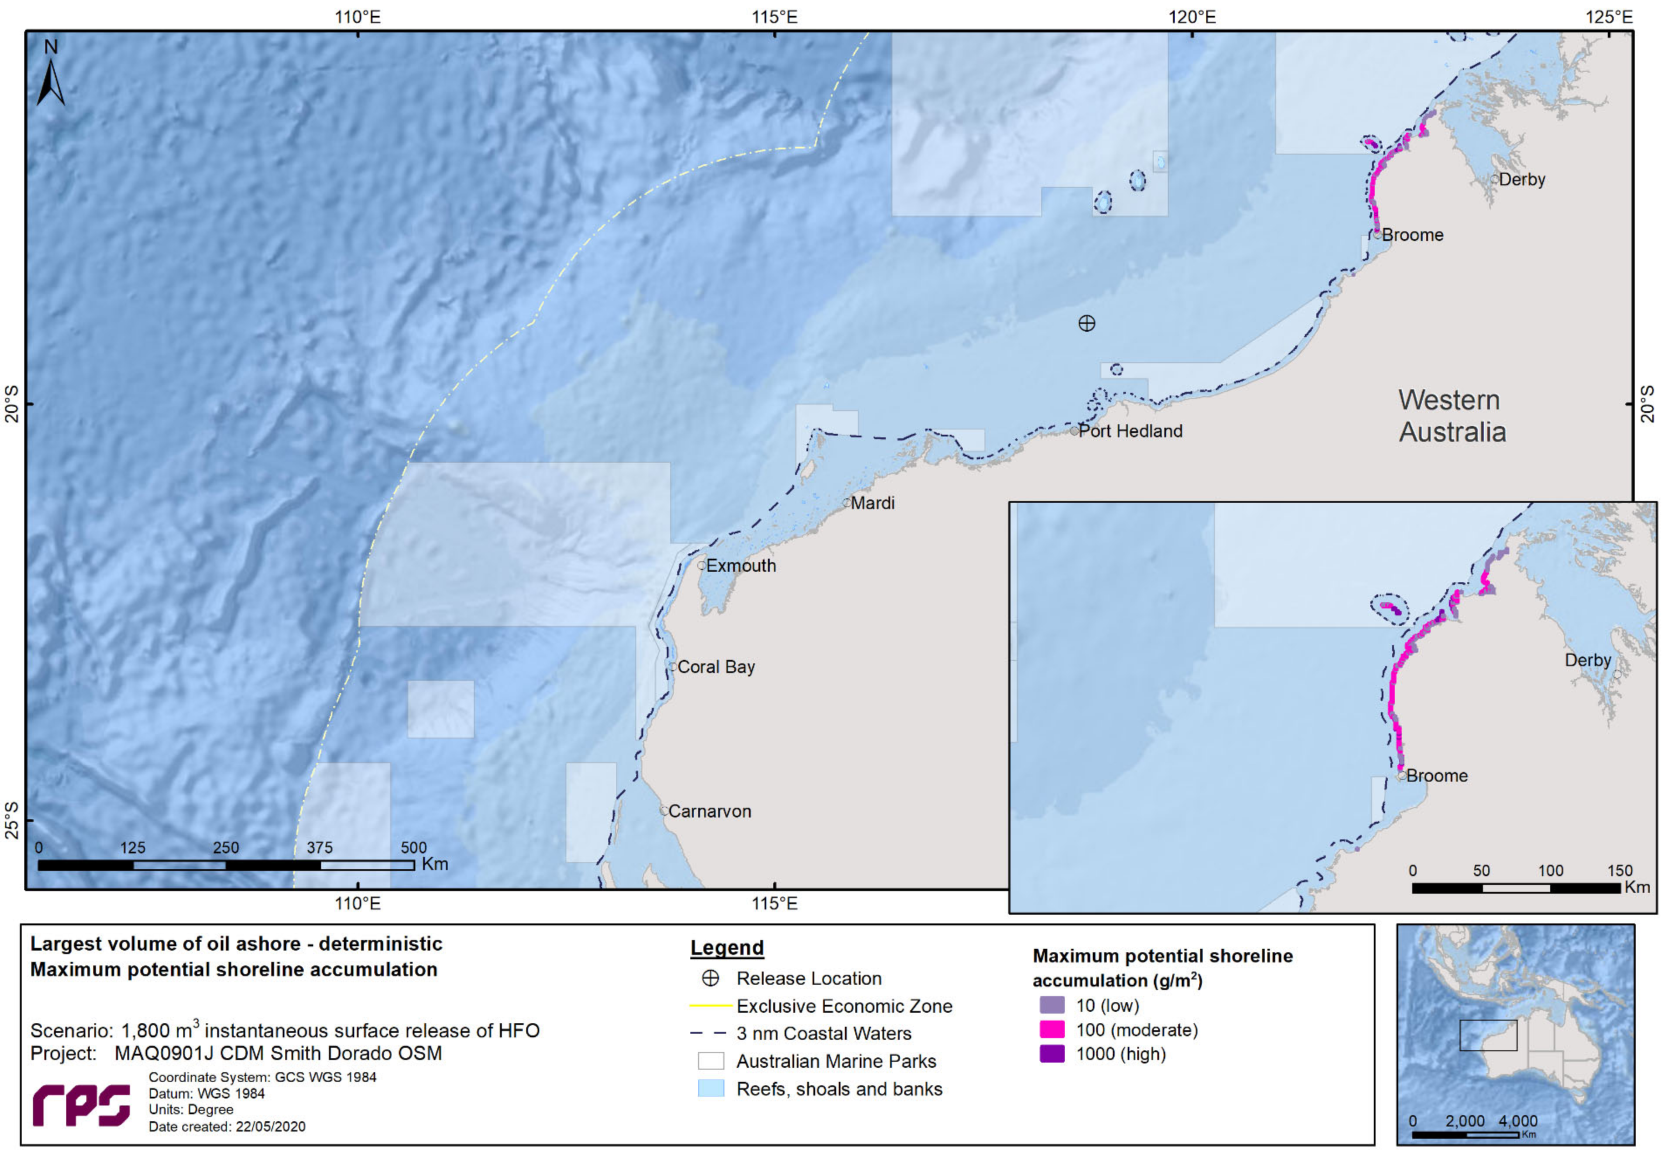

Figure 9.94 Potential shoreline accumulation for the simulation with the largest volume of oil ashore. Results are based on an instantaneous surface release of 1,800 m³ of HFO at the FPSO, tracked for 56 days, 8 am on the 19th of December 2015.

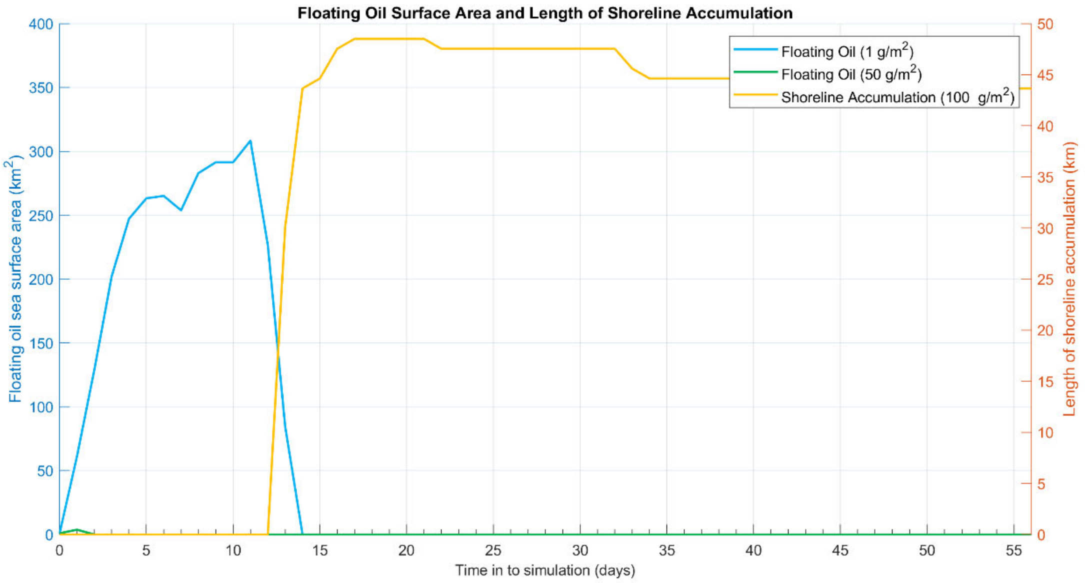

Figure 9.95 Time series of the area of visible (≥1 g/m²) and actionable floating oil (≥50 g/m²) on the sea surface and length of actionable shoreline oil (≥100 g/m²) for the simulation with the largest volume of oil ashore. Results are based on an instantaneous surface release of 1,800 m³ of HFO at the FPSO, tracked for 56 days, 8 am on the 19th of December 2015.

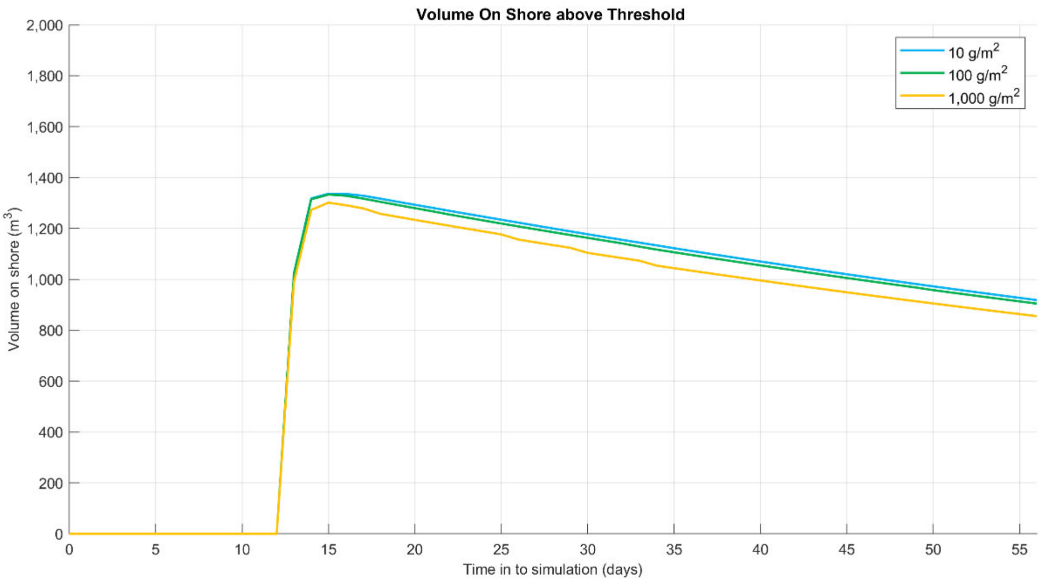

Figure 9.96 Time series of the volume on shore at the low (10-100 g/m²), moderate (100-1,000 g/m²) and high (≥ 1,000 g/m²) thresholds for the simulation with the largest volume of oil ashore. Results are based on an instantaneous surface release of 1,800 m³ of HFO at the FPSO, tracked for 56 days, 8 am on the 19th of December 2015.

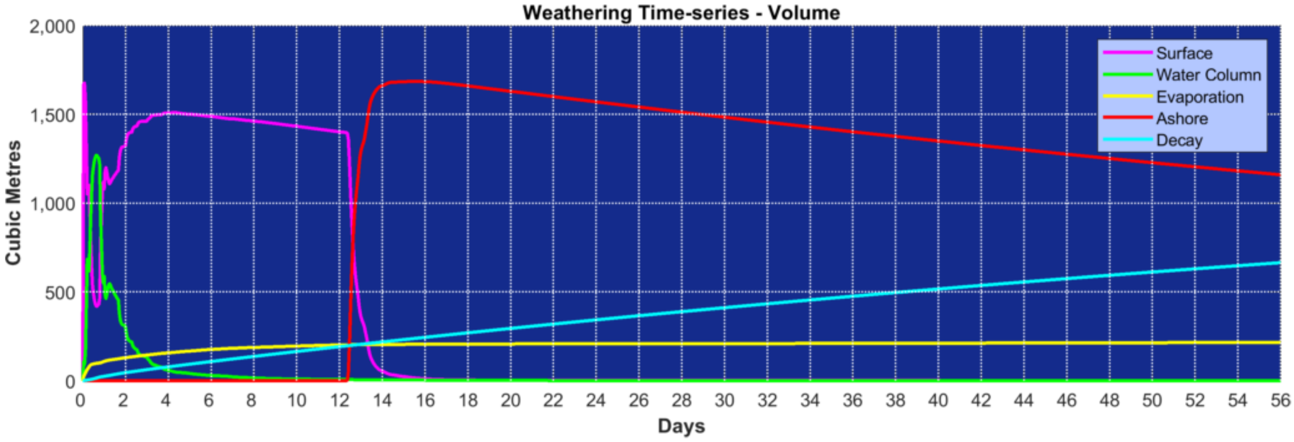

Figure 9.97 Predicted weathering and fates graph for the single spill simulation with the largest volume of oil ashore. Results are based on an instantaneous surface release of 1,800 m^3 of HFO at the FPSO, tracked for 56 days, 8 am on the 19th of December 2015.

9.5.2.2 Deterministic Case: Longest length of oiled shoreline

The deterministic simulation that resulted in the longest length of oiled shoreline above 100 g/m^2 was identified during summer conditions as run number 19, which commenced at 5 pm on the 5th of December 2014.

Exposure from floating oil (swept area) and potential shoreline accumulation over the entire simulation are presented in Figure 9.98 and Figure 9.99. Floating oil exposure was predicted to the northeast from the release location with shoreline accumulation occurring on the Broome coastline.

Figure 9.100 displays the time series of the area and length of visible oil (≥1 g/m^2) and actionable floating oil exposure on the sea surface (≥50 g/m^2) and actionable shoreline oil (≥100 g/m^2) over the 56-day simulation. The maximum area of visible oil on the sea surface was predicted to occur 12 days after the spill started and covered approximately 424 km^2. While the maximum length of actionable shoreline oiled (above 100 g/m^2) at any given time was 154 km, approximately 50 days into the simulation.

Figure 9.101 is a time series of the volume on shore at the low (10-100 g/m^2), moderate (100-1,000 g/m^2) and high (≥ 1,000 g/m^2) thresholds.

Figure 9**.**102 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 245 m^3 (13%) spilled oil was lost to the atmosphere through evaporation. Approximately 661 m^3 (37%) of the HFO was predicted to have decayed, while <0.1 m^3 (<0.1%) remained within the water column and 895 m^3 (50%) was predicted to remain on the shoreline.

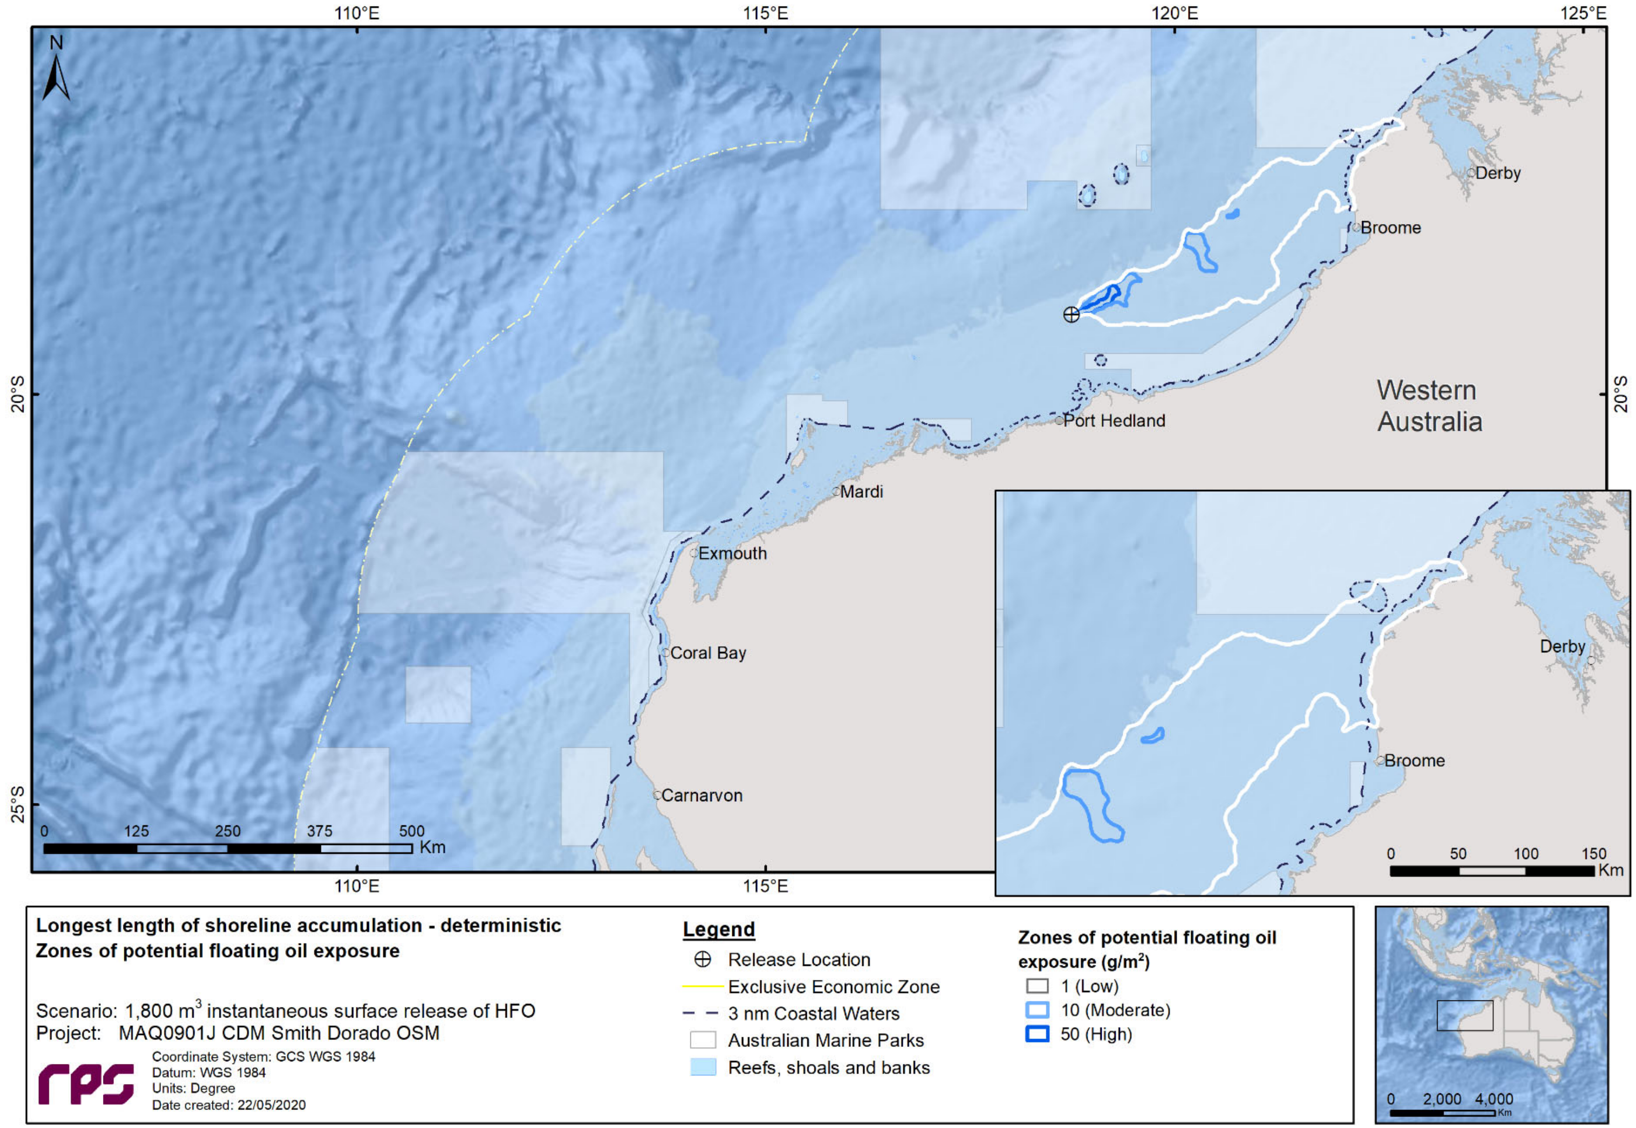

Figure 9.98 Exposure from floating oil (over the 56 day simulation) for the simulation with the longest length of shoreline with accumulation above 100 g/m^2. Results are based on an instantaneous surface release of 1,800 m^3 of HFO at the FPSO, starting 5 pm on the 5th of December 2014.

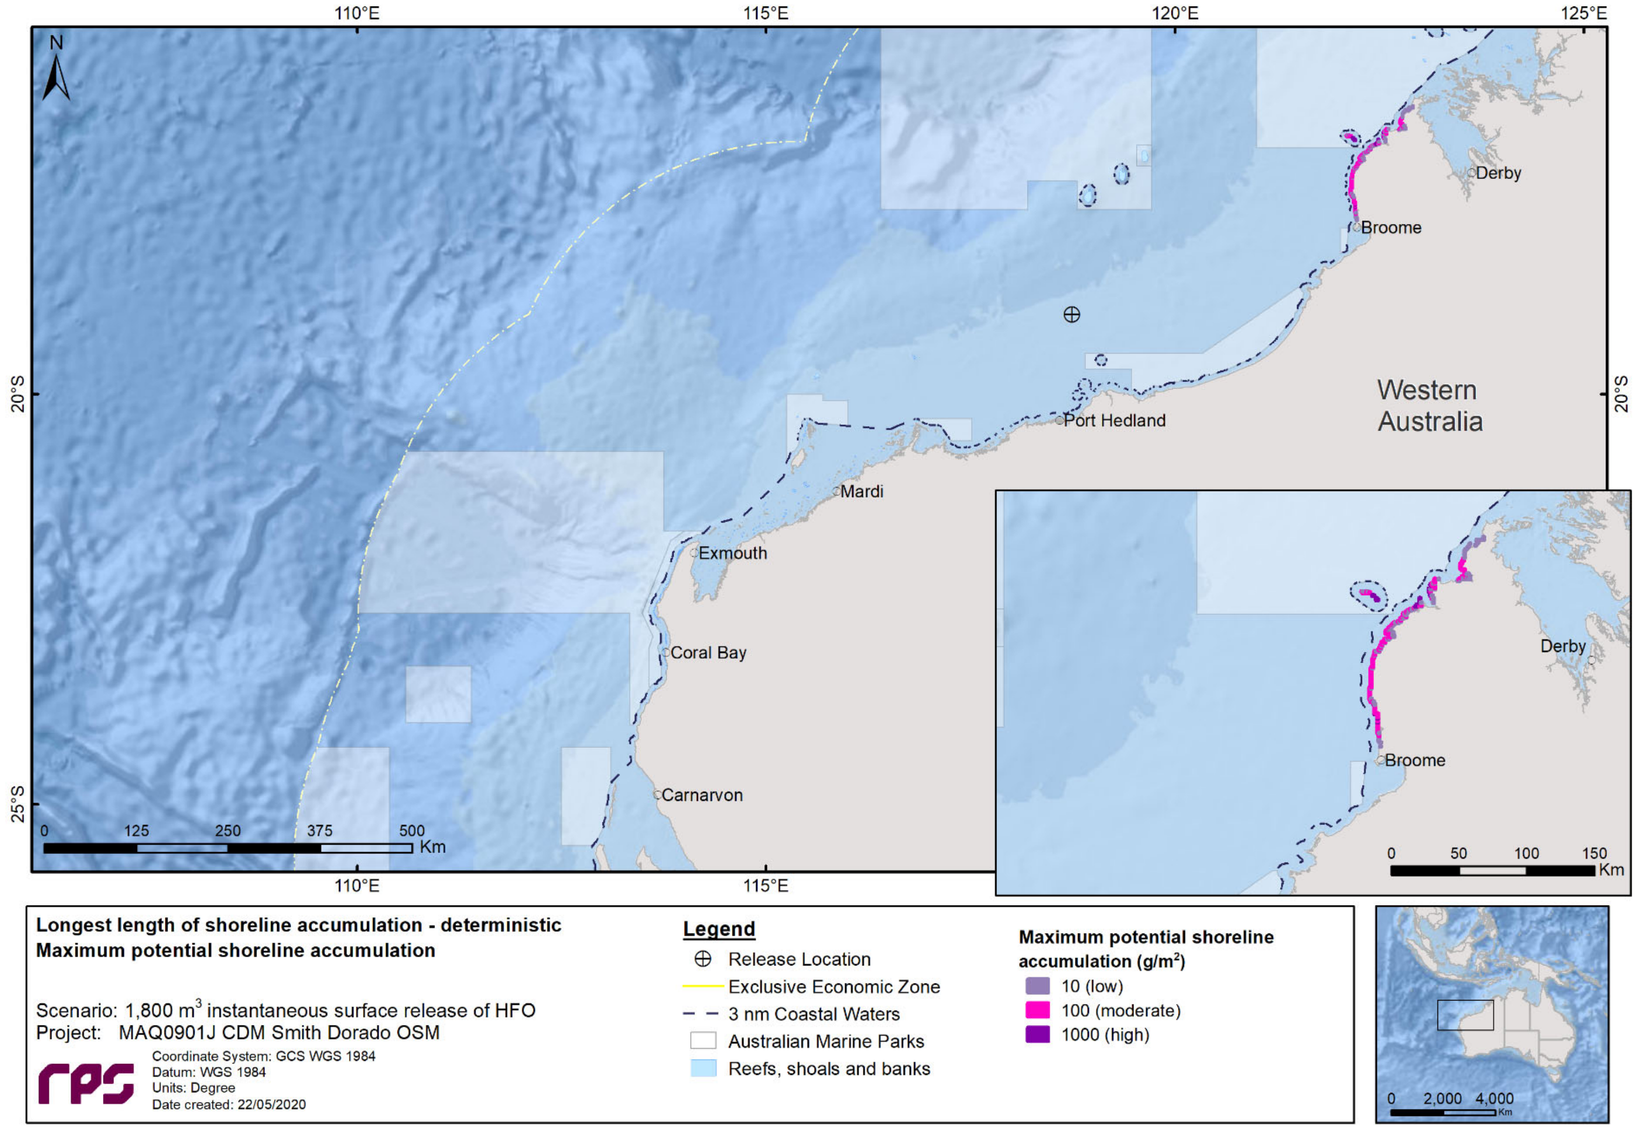

Figure 9.99 Potential shoreline loading for the simulation with the longest length of shoreline with accumulation above 100 g/m^2. Results are based on an instantaneous surface release of 1,800 m^3 of HFO at the FPSO, tracked for 56 days, 5 pm on the 5th of December 2014.

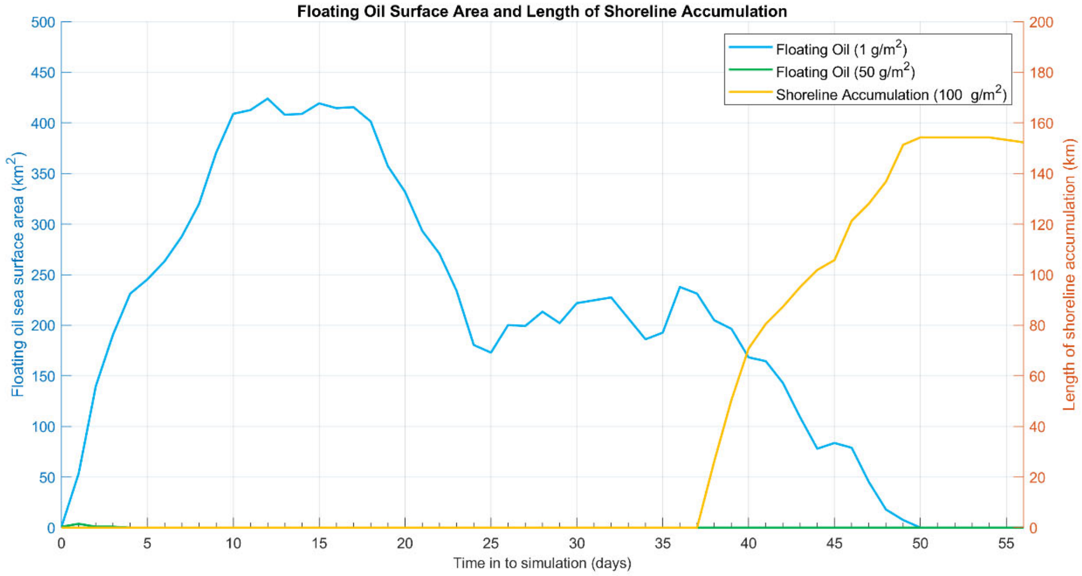

Figure 9.100 Time series of the area of visible (≥1 g/m²) and actionable floating oil (≥50 g/m²) on the sea surface and length of actionable shoreline oil (≥100 g/m²) for the simulation with the longest length of shoreline with accumulation above 100 g/m². Results are based on an instantaneous surface release of 1,800 m³ of HFO at the FPSO, tracked for 56 days, 5 pm on the 5th of December 2014.

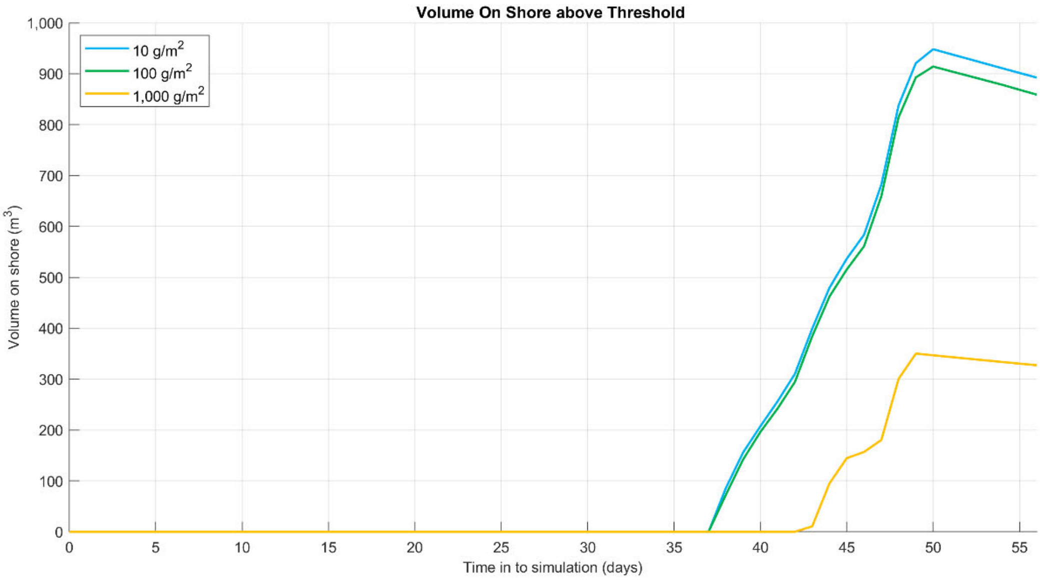

Figure 9.101 Time series of the mass on shore at the low (10-100 g/m²), moderate (100-1,000 g/m²) and high (≥ 1,000 g/m²) thresholds for the simulation with the longest length of shoreline with accumulation above 100 g/m². Results are based on an instantaneous surface release of 1,800 m³ of HFO at the FPSO, tracked for 56 days, 5 pm on the 5th of December 2014.

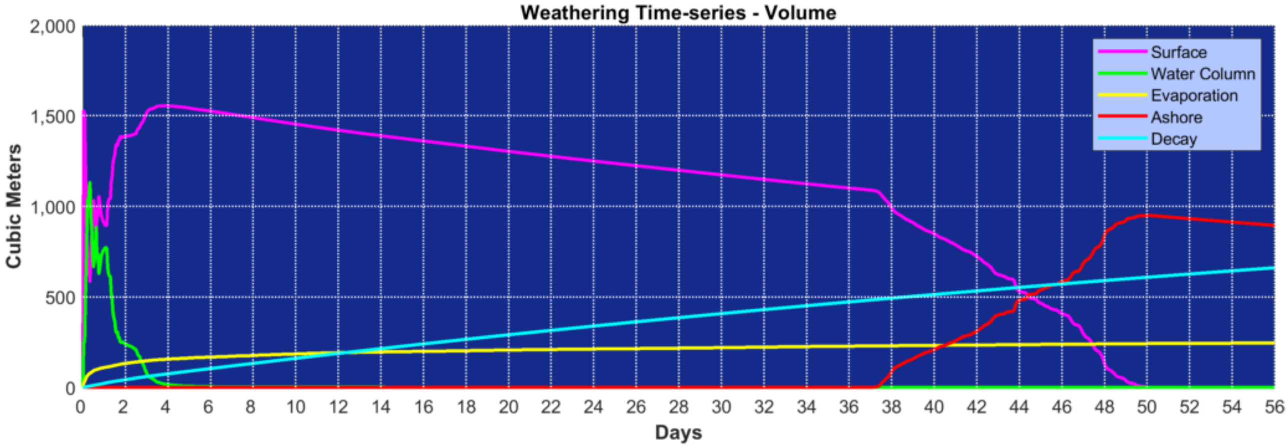

Figure 9.102 Predicted weathering and fates graph for the single spill simulation with the longest length of shoreline with accumulation above 100 g/m^2. Results are based an instantaneous surface release of 1,800 m^3 of HFO at the FPSO, tracked for 56 days, 5 pm on the 5th of December 2014.

9.5.3 Seasonal analysis

9.5.3.1 Floating Oil Exposure

Table 9.38 summarises the maximum distances from the release location to floating oil exposure zones for each season. The maximum distance from the release location to the low (1–10 g/m^2), moderate (10–50 g/m^2) and high (≥ 50 g/m^2) exposure thresholds was 2,143.4 km west-northwest (transitional), 1,707.1 km west-northwest (winter) and 1,013.6 km west-southwest (transitional), respectively.

Images of floating oil exposure zones are depicted in Figure 9.103, Figure 9.104 and Figure 9.105 for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively.

Table 9.39 to Table 9.41 summarise the potential floating oil exposure to individual sensitive receptors (refer Section 7.3) for each season.

Nine AMPs are within the predicted zone of floating oil exposure (at the low threshold) during summer conditions, 6 for transitional and 5 for winter conditions. The Argo-Rowley Terrace AMP recorded the highest probability of exposure of 53% during transitional conditions. The shortest time before exposure at AMPs was recorded at Montebello, which was predicted to take 3.88 days during transitional conditions.

There are 14 RSB within the low exposure zone across the 3 seasons and 13 during summer. Imperieuse Reef recorded the highest probability of exposure at 20%, which occurred during transitional conditions, with the minimum time before exposure at 11.6 days.

Floating oil was predicted to cross WA State Waters during every season at the low threshold, with probabilities ranging from 12% (winter) to 69% (summer). The minimum time before oil crossed the WA State Waters boundary was 10.25 days, recorded for a spill commencing during transitional conditions.

Table 9.38 Maximum distance and direction from the release location to floating oil exposure thresholds. Results are based on an instantaneous surface release of 1,800 m^3 of HFO at the FPSO. The results were calculated from 100 spill simulations per season.

Season	Distance and direction	Exposure from floating oil		
		Low (1-10 g/m^2)	Moderate (10-50 g/m^2)	High (≥50 g/m^2)
Summer	Max. distance from release site (km)	1,433.5	1,010.9	984
	Max distance from release site (km) (99th percentile)	1,222.6	844.1	707.4
	Direction	West-Northwest	West-Southwest	West-Southwest
Transitional	Max. distance from release site (km)	2,143.4	1,489.4	1,013.6
	Max distance from release site (km) (99th percentile)	1,611.5	1,152.5	933.6
	Direction	West-Northwest	West-Northwest	West-Southwest
Winter	Max. distance from release site (km)	1,923.9	1,707.1	695.4
	Max distance from release site (km) (99th percentile)	1,581.0	1,096.6	566.0
	Direction	West-Northwest	West-Northwest	West

Table 9.39 Summary of the potential floating oil exposure to individual receptors. Results are based on an instantaneous surface release of 1,800 m³ of HFO at the FPSO during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Receptor		Probability of floating oil exposure (%)			Minimum time before floating oil exposure (days)		
		Low (1-10 g/m²)	Moderate (10-50 g/m²)	High (≥50 g/m²)	Low (1-10 g/m²)	Moderate (10-50 g/m²)	High (≥50 g/m²)

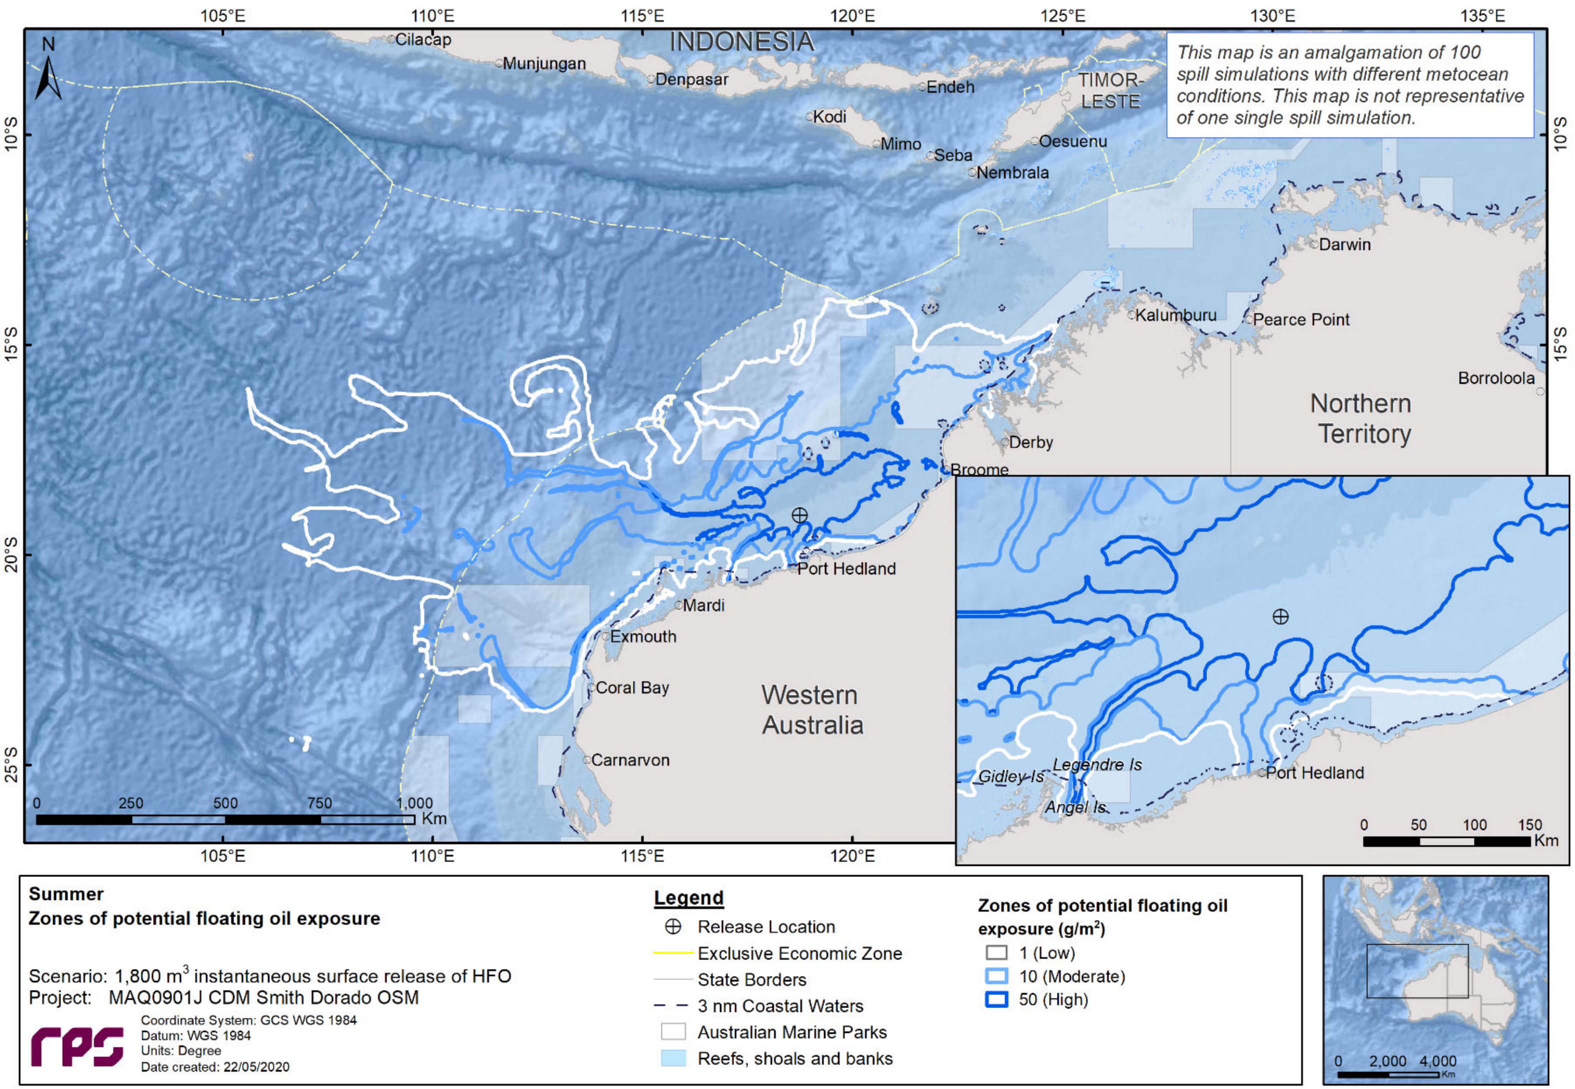

Figure 9.103 Predicted zones of potential floating oil resulting from an instantaneous surface release of 1,800 m³ of HFO at the FPSO. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

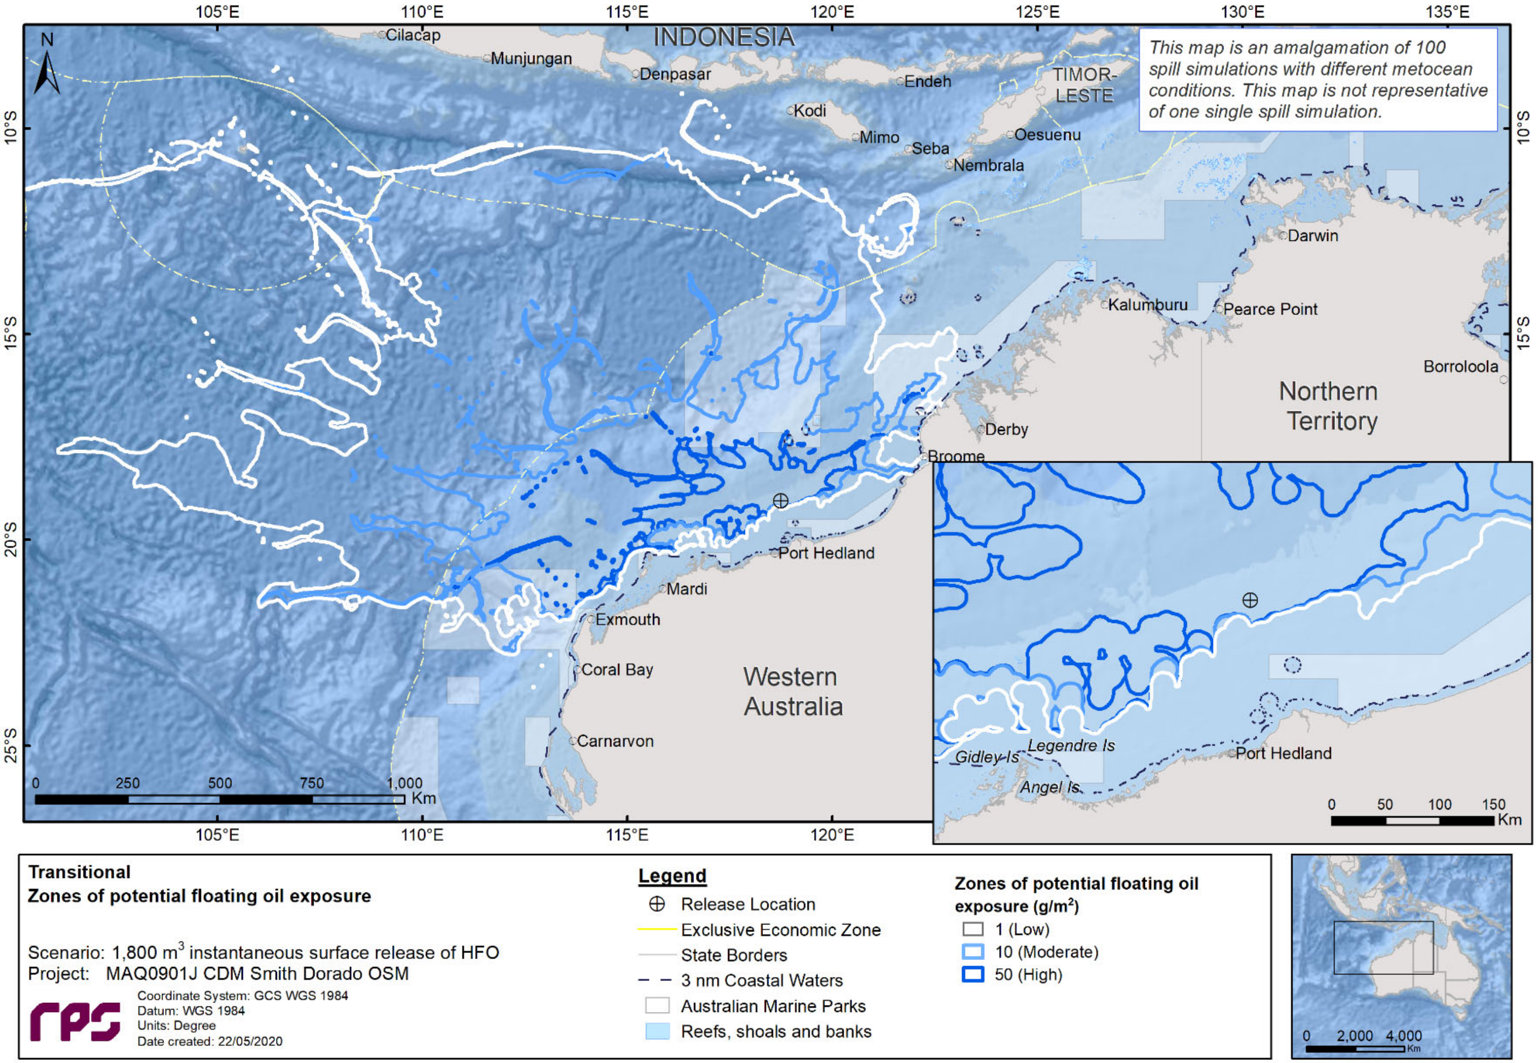

Figure 9.104 Predicted zones of potential floating oil resulting from an instantaneous surface release of 1,800 m^3 of HFO at the FPSO. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

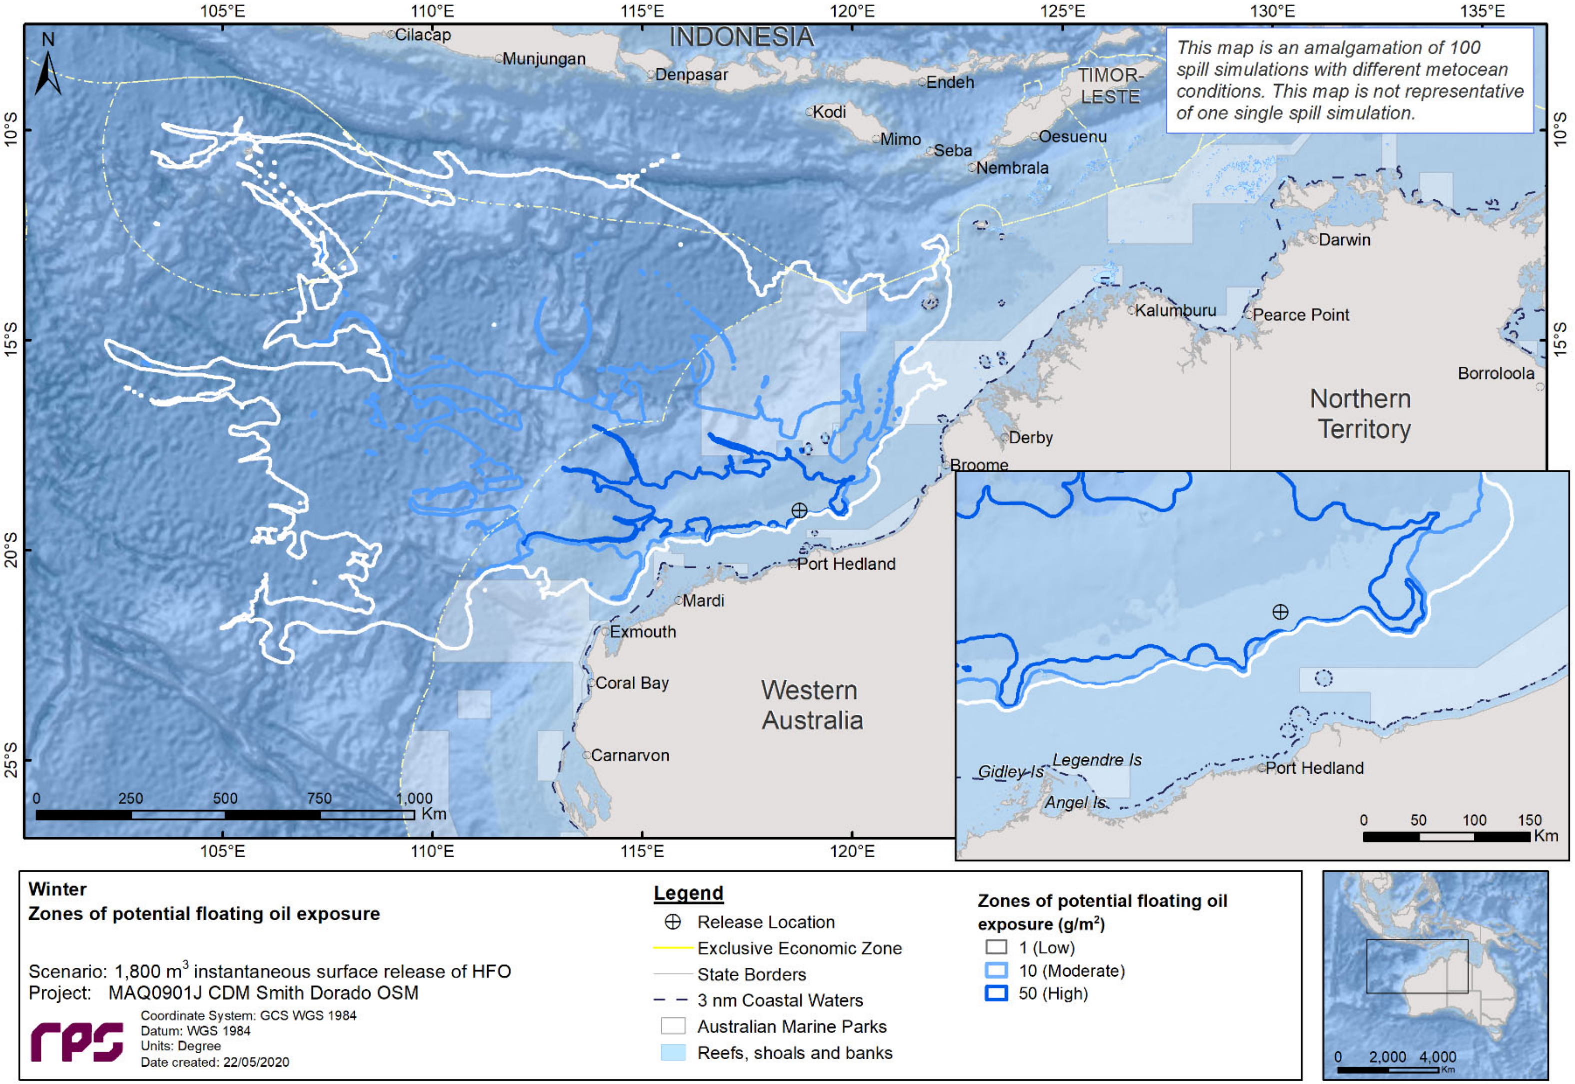

Figure 9.105 Predicted floating oil exposure zones resulting from an instantaneous surface release of 1,800 m³ of HFO at the FPSO. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.5.3.2 Shoreline Accumulation

Table 9.42 presents a summary of the predicted oil accumulation on any shoreline for all three seasons assessed. The probability of oil accumulation at, or above, the low threshold (10-100 g/m^2) during summer, transitional and winter seasons was 72%, 31% and 16%, respectively. The minimum time before oil accumulation above the low threshold was approximately 11.67 days during transitional conditions. The greatest volume of oil ashore was 1,684.5 m^3 for a spill commencing in the summer period.

Table 9.43 to Table 9.45 summarise the oil accumulation to individual shoreline receptors assessed for all seasonal conditions. Based on the 100 simulations per season and across the 3 seasons, a total of 36 sensitive (refer Section 7.3) receptors were predicted to record oil accumulation at the low threshold, with Broome recording the highest probability of 45% during summer conditions. The quickest time before shoreline accumulation was predicted during transitional conditions (11.67 days) at Imperieuse Reef. The greatest volume of oil ashore of 1,684.5 m^3 and the maximum length of shoreline with accumulation at the low threshold was 252.3 km, both occurred at Broome during summer conditions.

The maximum potential shoreline loading at low, moderate and high accumulation thresholds are depicted in Figure 9.106, Figure 9.107 and Figure 9.108 for spills commencing during summer, transitional and winter conditions, respectively.

Table 9.42 Summary of oil accumulation on any shoreline. Results are based on an instantaneous surface release of 1,800 m^3 of HFO at the FPSO during all seasonal conditions. The results were calculated from 100 spill simulations per season.

Shoreline Statistics	Summer	Transitional	Winter
Probability of shoreline accumulation at, or above **10 g/m^2** (%)	72	31	16
Minimum time before shoreline accumulation at, or above **10 g/m^2** (days)	12.3	11.7	13.42
Maximum volume of oil ashore (m^3) from a single simulation	1,684.5	1,383.0	957.8
Average volume of oil ashore (m^3) for all simulations predicted to reach the shorelines	812.3	142.0	128.8
Maximum length of shoreline accumulation at or above **10 g/m^2** (km) from a single simulation	259.0	159.0	112.0
Average length of shoreline accumulation at or above **10 g/m^2** (km) for all simulations predicted to reach the shorelines	85.7	29.3	24.4
Maximum length of shoreline accumulation at or above **100 g/m^2** (km) from a single simulation	160.0	77.0	84.0
Average length of shoreline accumulation at or above **100 g/m^2** (km) for all simulations predicted to reach the shorelines	53.6	15.2	12.9
Maximum length of shoreline accumulation at or above **1,000 g/m^2** (km) from a single simulation	44.0	31.0	28.0
Average length of shoreline accumulation at or above **1,000 g/m^2** (km) for all simulations predicted to reach the shorelines	25.5	6.7	7.7

Table 9.43 Summary of oil accumulation on individual shorelines. Results are based on an instantaneous surface release of 1,800 m³ of HFO at the FPSO during summer (October to March) conditions. The results were calculated from 100 spill simulations.

9.5.3.3 Entrained Hydrocarbons

Images of entrained hydrocarbon exposure zones in the 0-10 m depth layer are depicted in Figure 9.109, Figure 9.110 and Figure 9.111 for the combined 100 spill simulations each commencing during summer, transitional and winter conditions, respectively. The results indicated that exposure at the low threshold was predicted to occur up to a maximum distance of 850 km (southwest) from the spill site during summer conditions. This distance reduced to 411 km (west-southwest) as the contact threshold increased to 100 ppb in summer conditions. The maximum distances for transitional and winter conditions at the low threshold were 506 km and 290 km, respectively. The maximum distances at the moderate threshold were reduced to 175 km for transitional and 125 km for winter conditions.

Table 9.46 to Table 9.48 summarise the probability of exposure to individual sensitive receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer for each season. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at their shallowest depth from the sea surface.

Three AMPs are within the low exposure zone for summer and 1 AMP (Montebello) during transitional conditions. Montebello AMP recorded the highest probability of exposure of 2% and the shortest time for entrained hydrocarbons to reach an AMP at the low threshold of 6.25 days, both during transitional conditions. No AMPs were predicted to be exposed from spills at the low threshold occurring during winter conditions.

No KEF receptors were predicted to be exposed by entrained hydrocarbons at the low threshold.

Entrained hydrocarbon exposure at the low threshold was predicted at Rankin Bank only during transitional conditions with a probability of 2%. The quickest time before exposure was 7 days.

Entrained hydrocarbons at the low (10-100 ppb) threshold were not predicted to cross into WA State Waters during any season.

Table 9.46 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer. Results are based on an instantaneous surface release of 1,800 m^3 of HFO at the FPSO during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of entrained hydrocarbon exposure		Minimum time (days) before hydrocarbon exposure		Maximum entrained hydrocarbon concentration (ppb)

9.5.3.4 Dissolved Hydrocarbons

Images of dissolved hydrocarbon exposure zones are depicted in Figure 9.112 and Figure 9.113 for the combined 100 spills each commencing during summer and transitional conditions, respectively. There was no dissolved hydrocarbon exposure during the winter conditions.

The results indicated exposure for the low threshold (10-50 ppb) was predicted to occur up to a distance of 42 km (northwest) and 215 km (west) from the spill site during summer and transitional conditions, respectively. No exposure at the moderate (50-400 ppb) or high (≥ 400 ppb) thresholds was predicted in any of the assessed seasons.

No KEF or RSB receptors were predicted to be exposed by dissolved hydrocarbons at the low threshold.

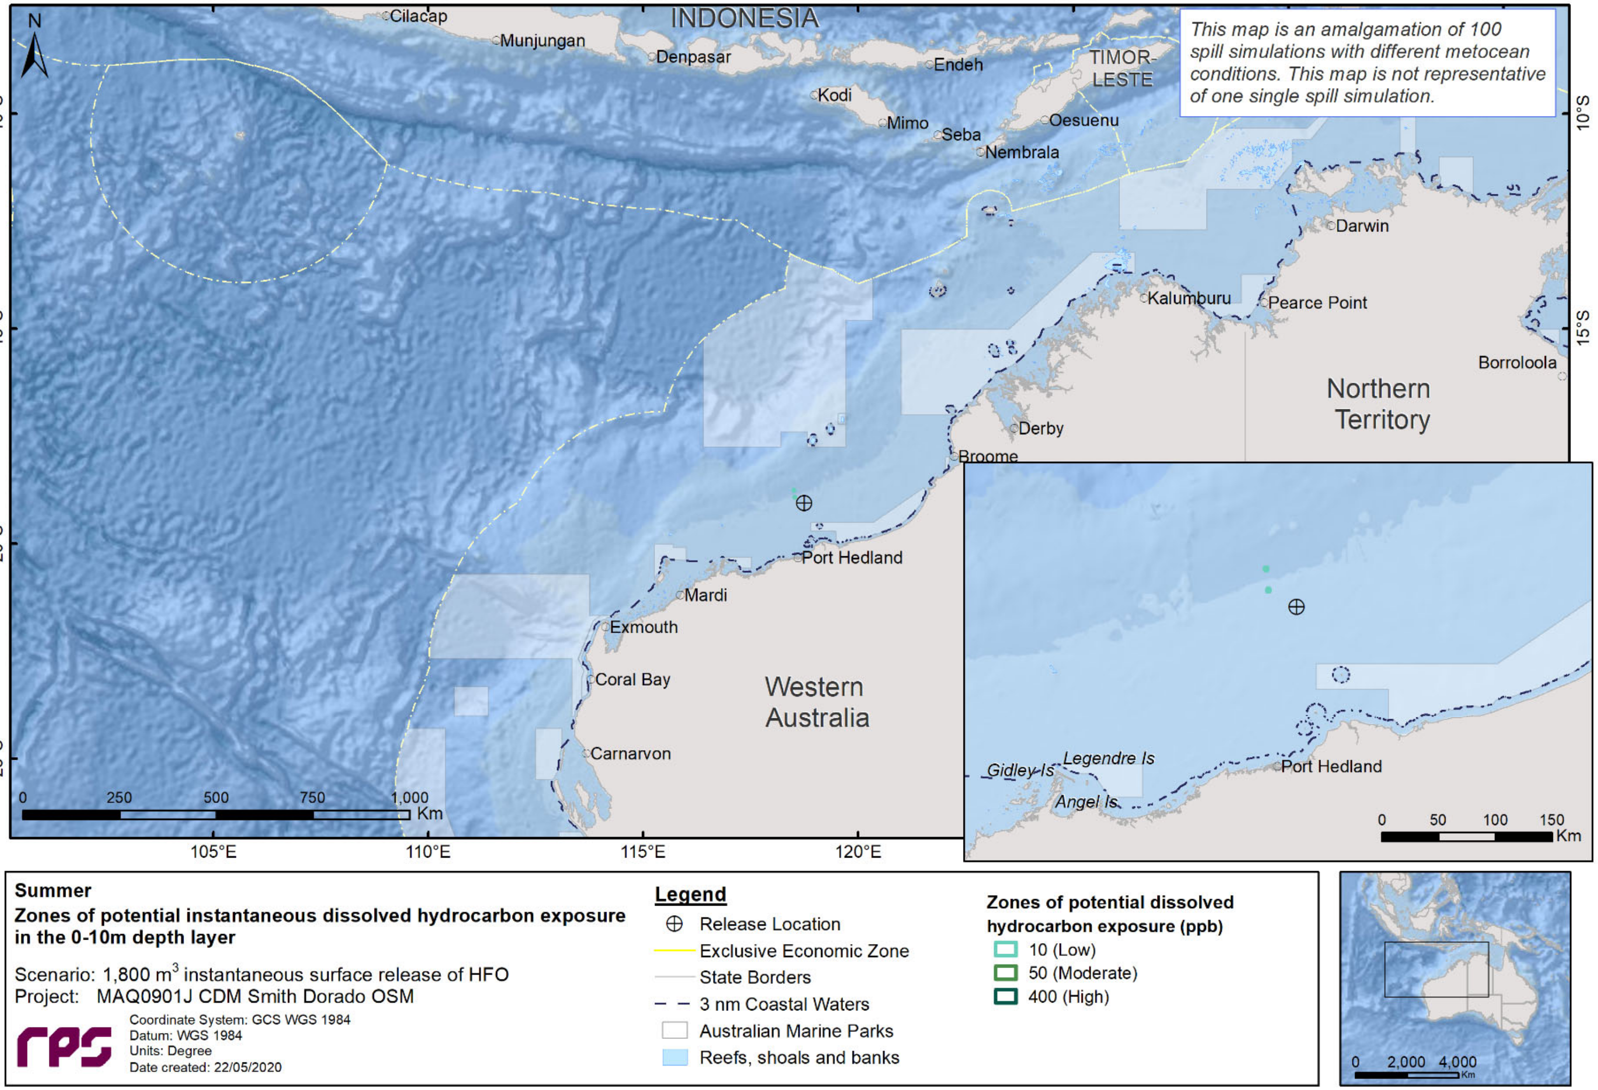

Figure 9.112 Predicted dissolved hydrocarbon exposure zones resulting from an instantaneous surface release of 1,800 m³ of HFO at the FPSO. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

9.6 Scenario 6: Simulation of an instantaneous surface release of crude representing a loss of contents from the FPSO

This scenario examined an instantaneous 10,108 m^3 surface release of crude from the FPSO, tracked for 42 days. A total of 300 simulations were run across three seasons; summer, transitional and winter (i.e. 100 spills per season). These are then combined and presented as exposures zones for each season (cumulative of 100 simulations) for the low, moderate and high thresholds.

Sections 9.6.1 presents overview of the EMBA based on combining the 300 spill simulations and Section 9.6.3 shows the seasonal (or stochastic) analysis. As there was no shoreline accumulation predicted for any spills during this scenario, the deterministic analysis (i.e. a single spill simulation) results presented in Section 9.6.2 are based on the largest area of floating oil (above 50 g/m^2) and the largest area of entrained hydrocarbons.

9.6.1 Overview

Figure 9.114 and Figure 9.115 are maps which encompass the full geographic EMBA derived by overlaying the combined results from all 300 spill simulations at both the low and moderate exposure thresholds, respectively.

Figure 9.116 and Figure 9.117 shows the annualised extent of floating oil and in-water (entrained and dissolved) exposure based on the low and moderate exposure thresholds, respectively, derived from all 300 spill simulations.

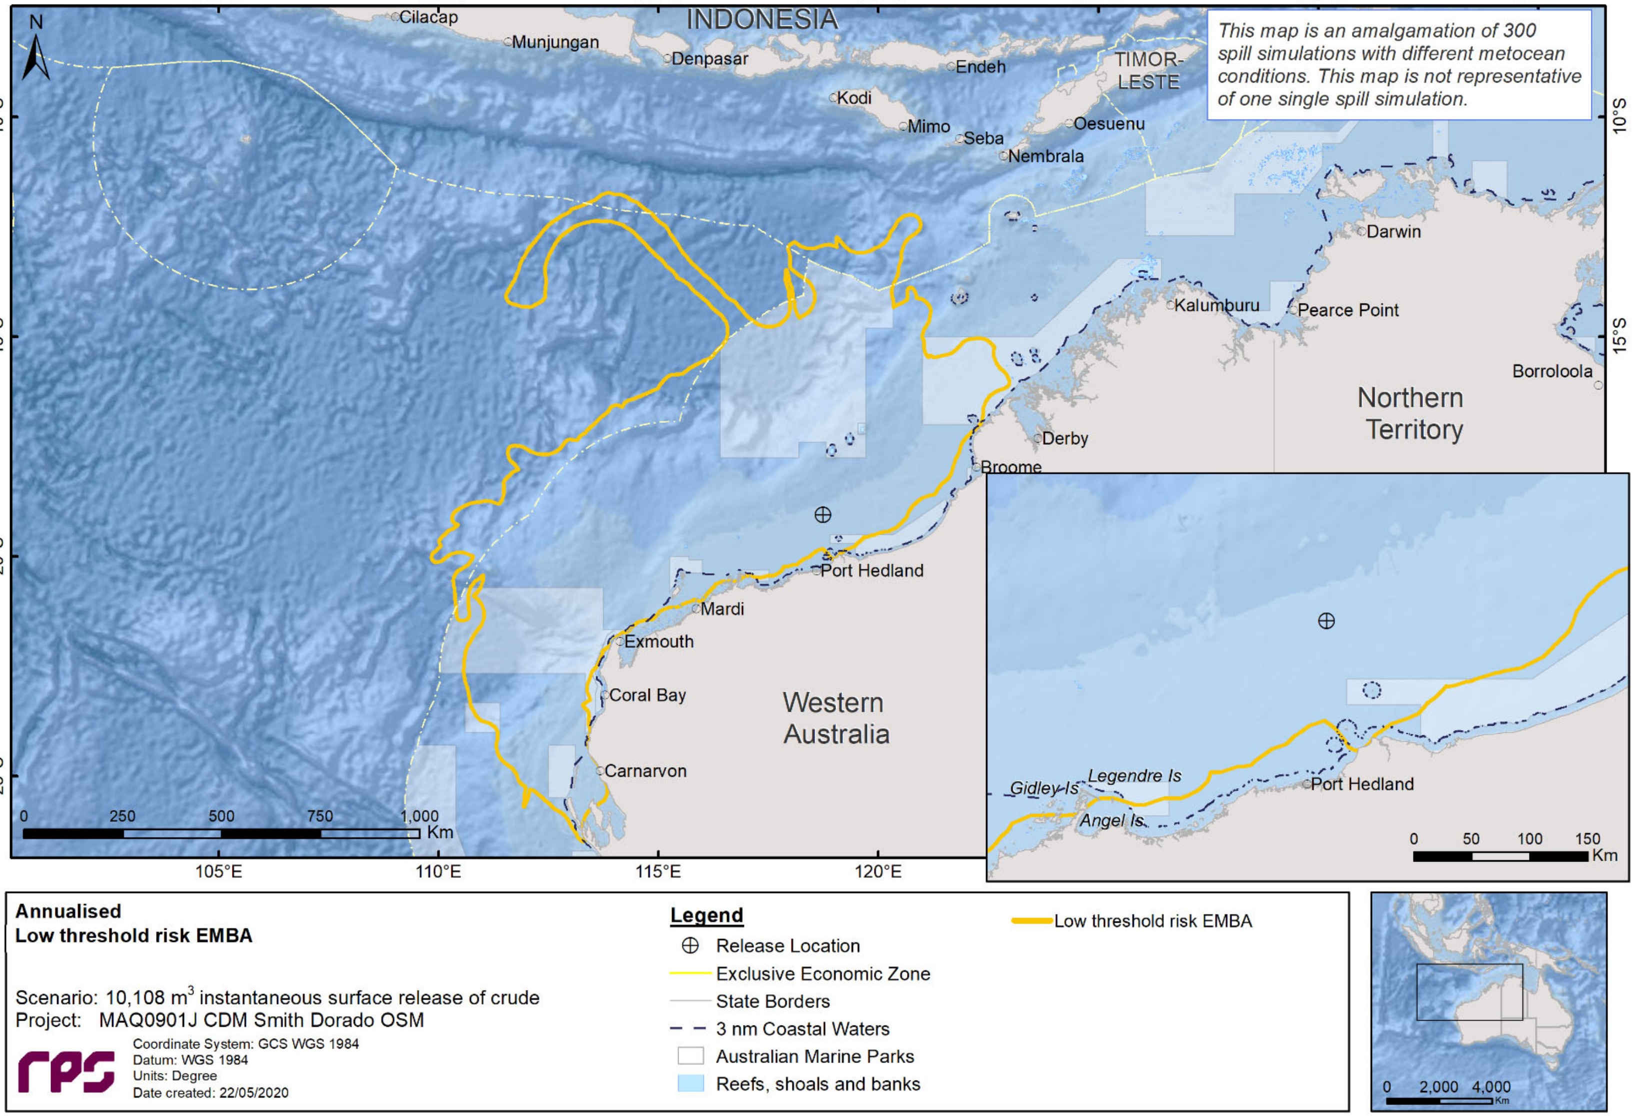

Figure 9.114 Predicted low threshold risk EMBA resulting from an instantaneous surface release of 10,108 m^3 of crude from the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 42 days.

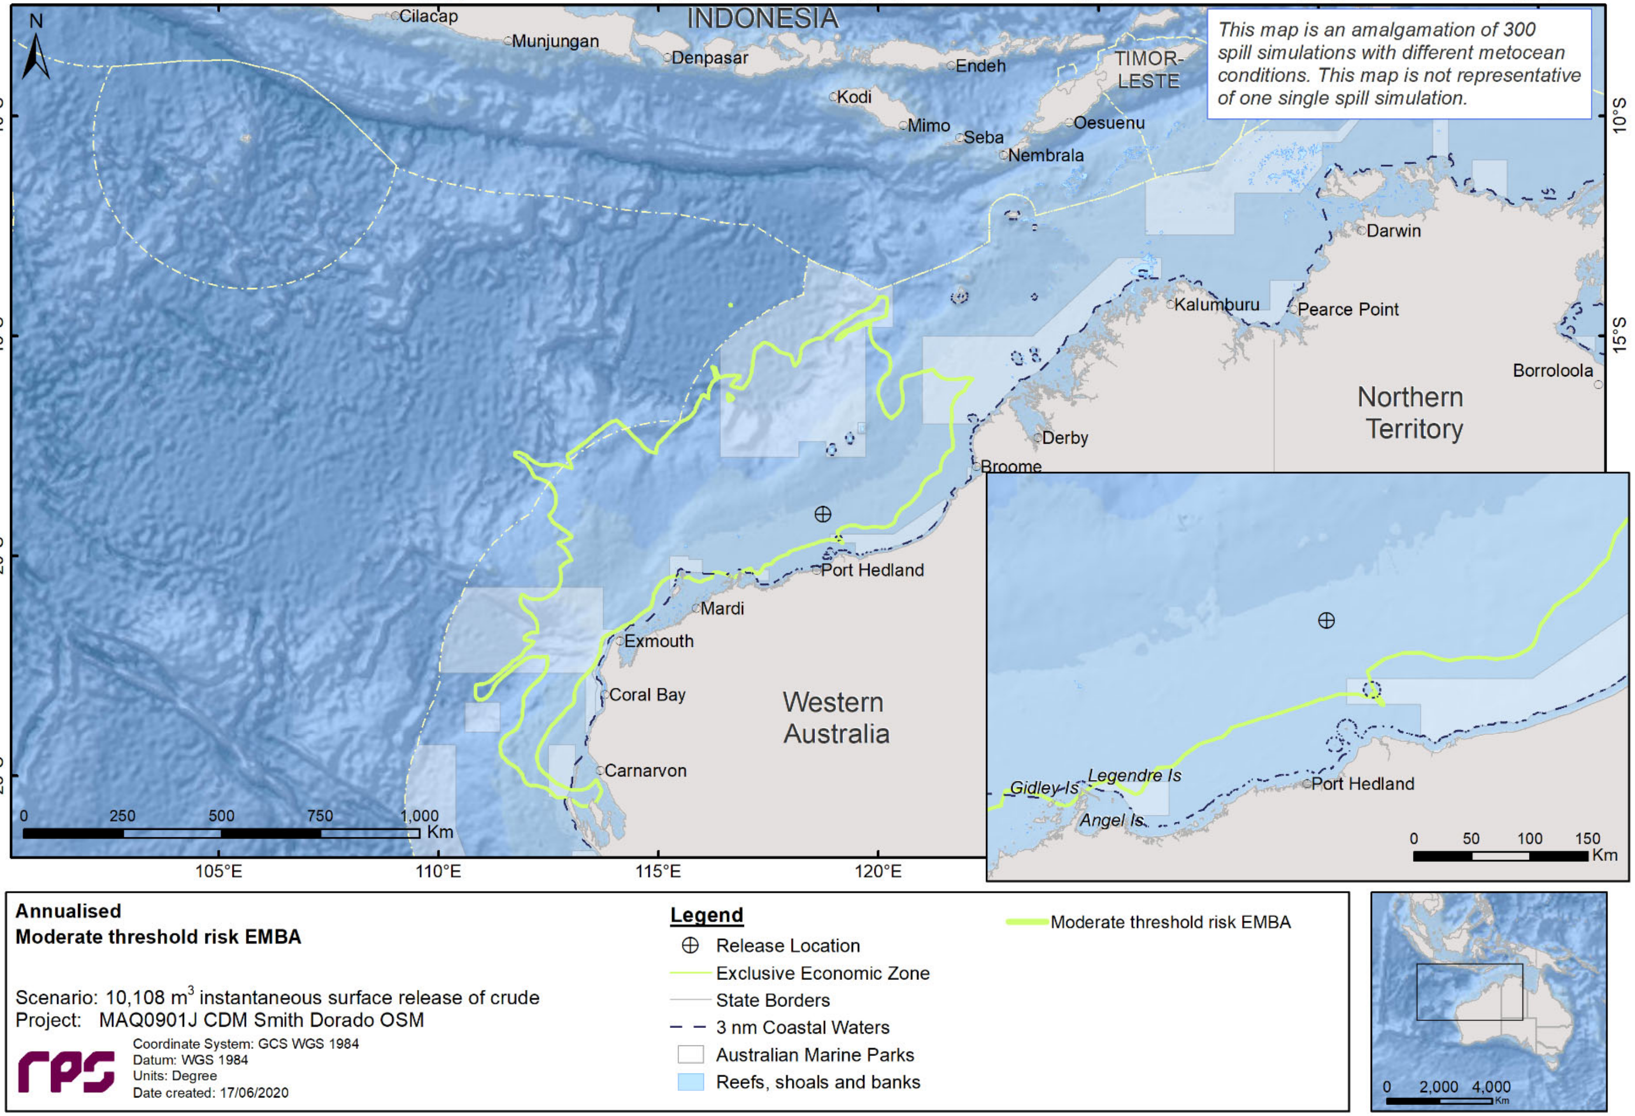

Figure 9.115 Predicted moderate threshold risk EMBA resulting from an instantaneous surface release of 10,108 m^3 of crude from the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 42 days.

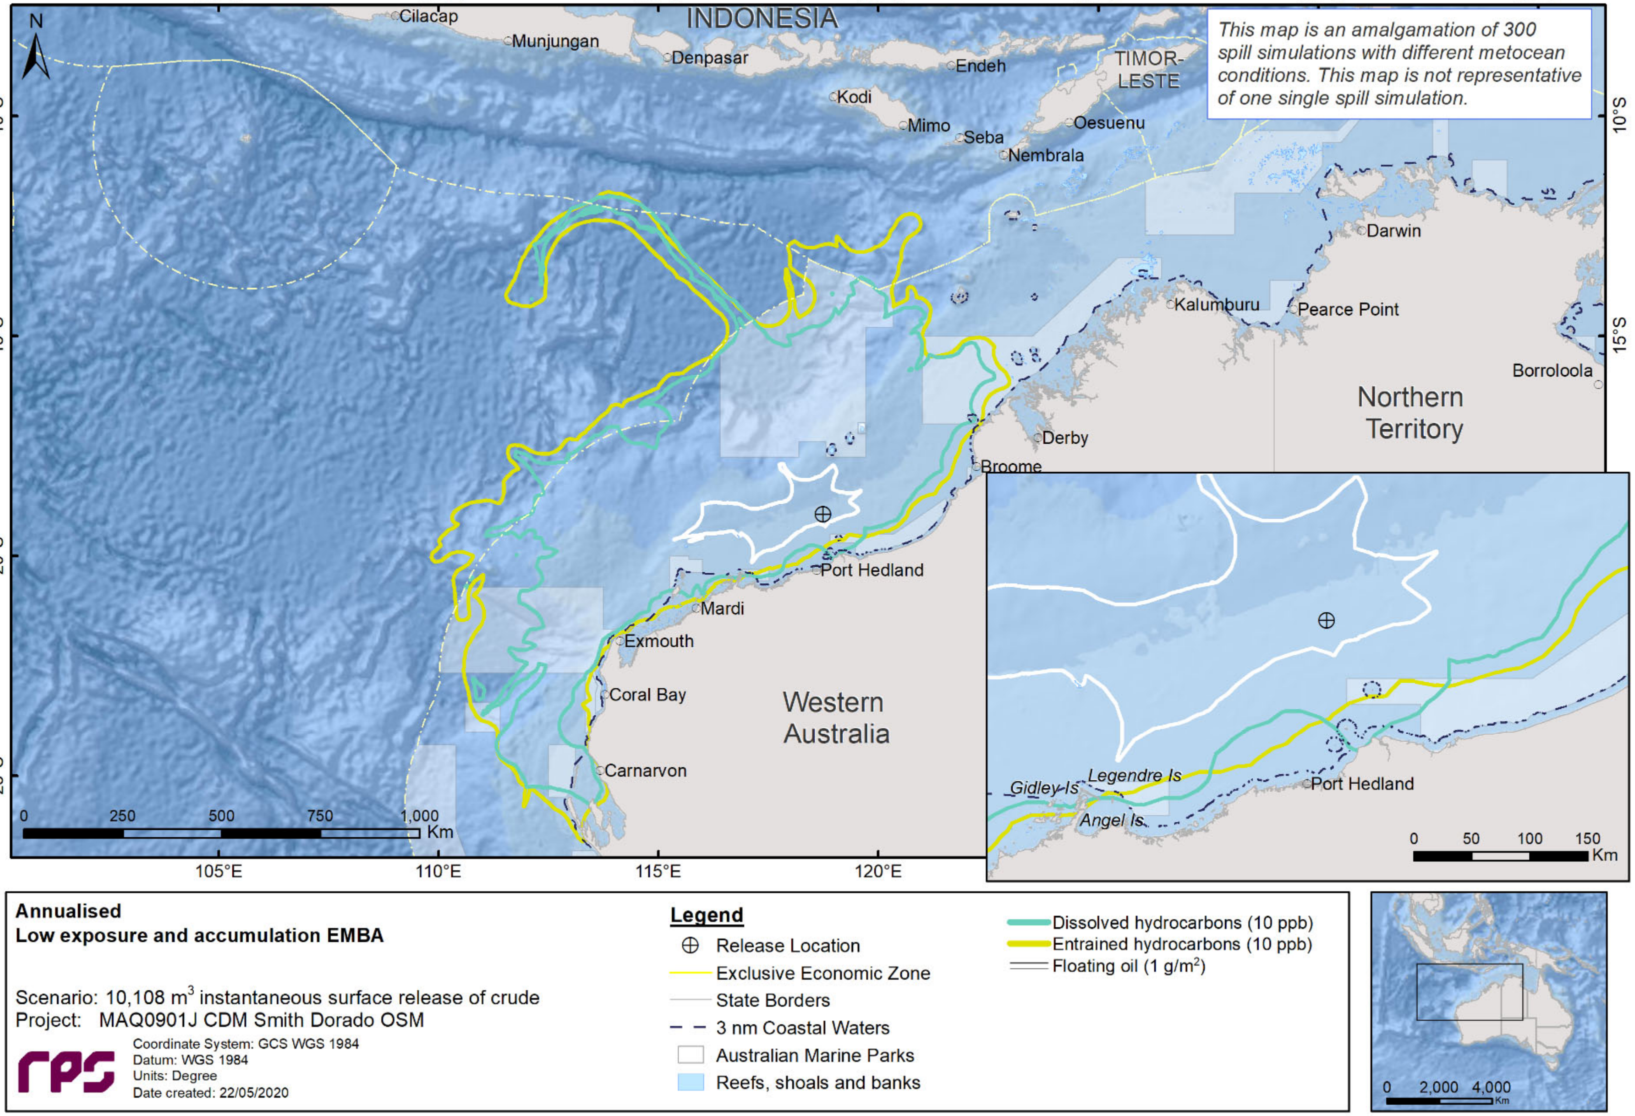

Figure 9.116 Annualised low threshold oil exposure resulting from an instantaneous surface release of 10,108 m^3 of crude from the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 42 days.

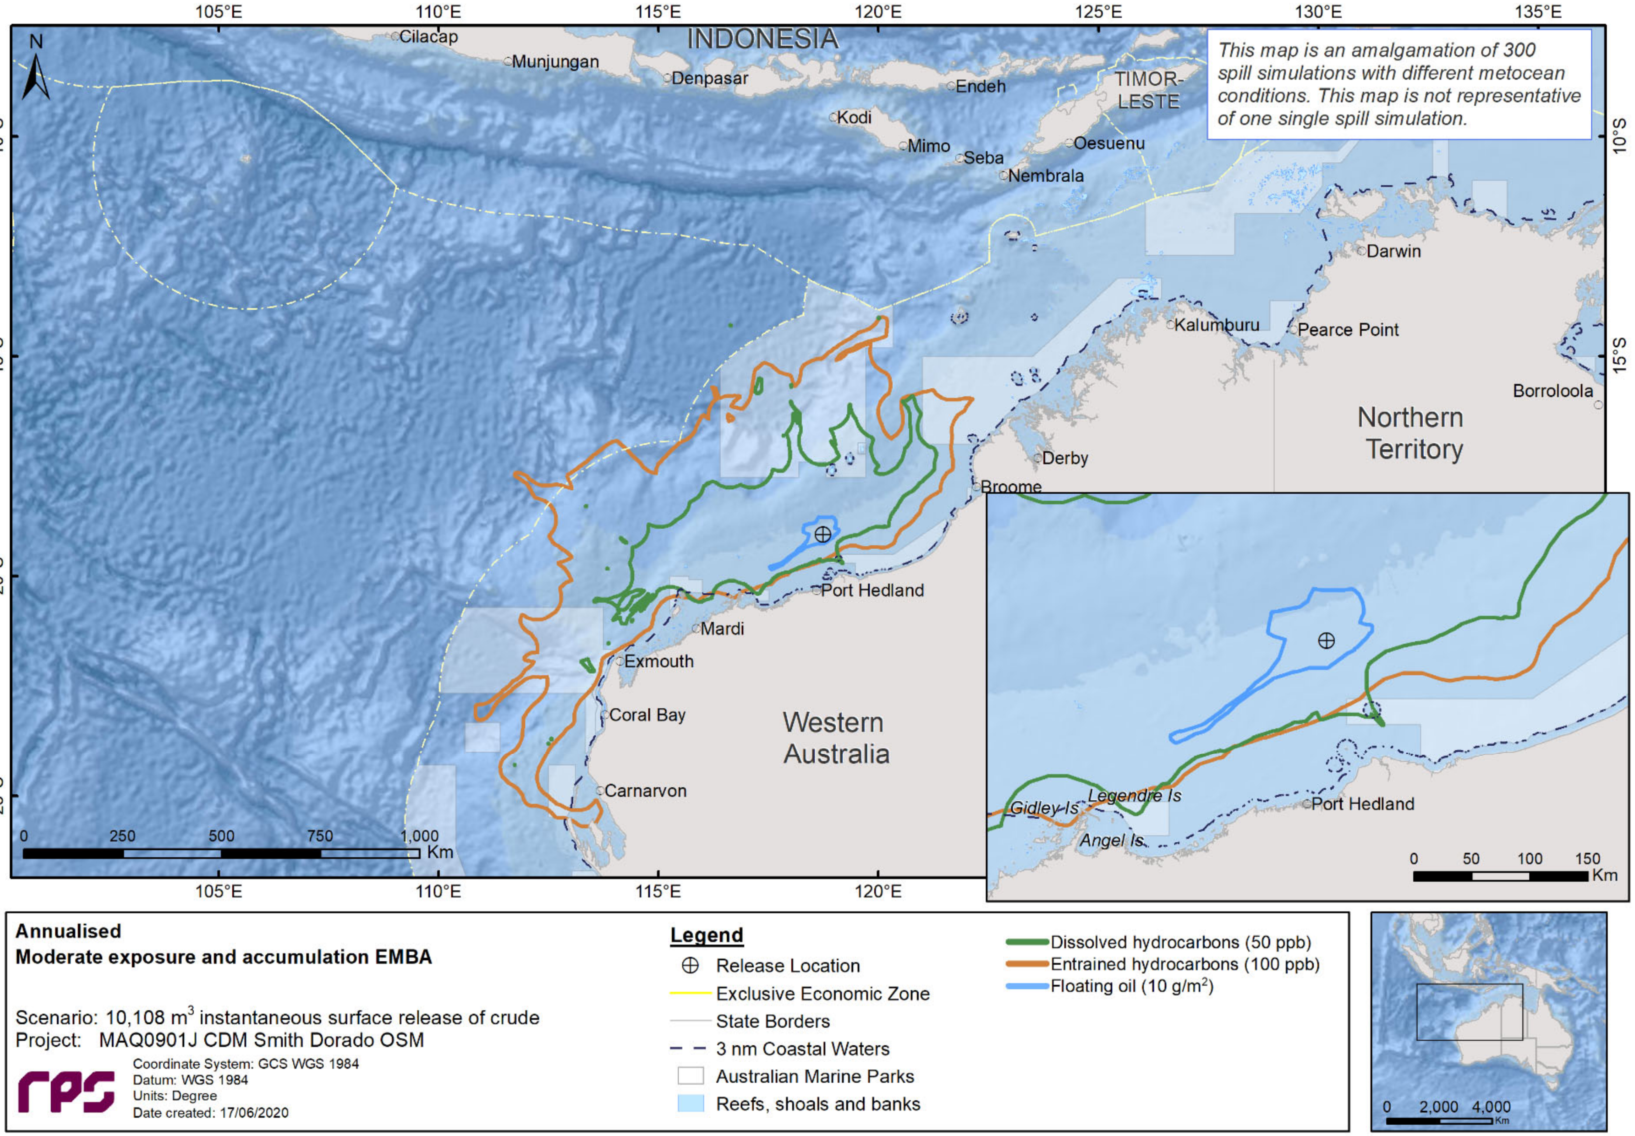

Figure 9.117 Annualised moderate threshold oil exposure resulting from an instantaneous surface release of 10,108 m^3 of crude from the FPSO. The annualised results were calculated from 300 spill simulations, which were tracked for 42 days.

9.6.2 Deterministic Analysis

The stochastic modelling results were assessed and the deterministic runs were identified and presented below based on the following criteria;

a. Largest area of floating oil above 50 g/m^2 (actionable floating oil); and

b. Largest area of entrained hydrocarbon exposure

9.6.2.1 Deterministic Case: Largest Area of Floating Oil above 50 g/m^2

The deterministic simulation that resulted in the largest area of floating oil above 50 g/m^2 (high or actionable surface oil threshold) was identified during summer conditions as run number 47, which commenced at 3 pm on the 26th of March 2017.

Exposure from floating oil (swept area) over the entire 42 day simulation is presented in Figure 9.118. Floating oil exposure was predicted to extend northwest from the release location up to a maximum distance of approximately 59 km at the low (1-10 g/m^2) threshold. Floating oil at the moderate (10-50 g/m^2) and high (≥50 g/m^2) thresholds were predicted to extend approximately 54 km and 47 km northeast of the release location, respectively.

Figure 9.119 displays the time series of the area of visible oil (≥1 g/m^2) and actionable floating oil (≥50 g/m^2) exposure on the sea surface over the 42-day simulation. The maximum area of coverage of visible oil on the sea surface was predicted to occur 4 days after the spill started and covered approximately 86 km^2.

Figure 9.120 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 6,724 m^3 (66%) spilled oil was lost to the atmosphere through evaporation. Approximately 2,012 m^3 (20%) of the crude was predicted to have decayed, while approximately 1,372 m^3 (14%) was predicted to remain within the water column.

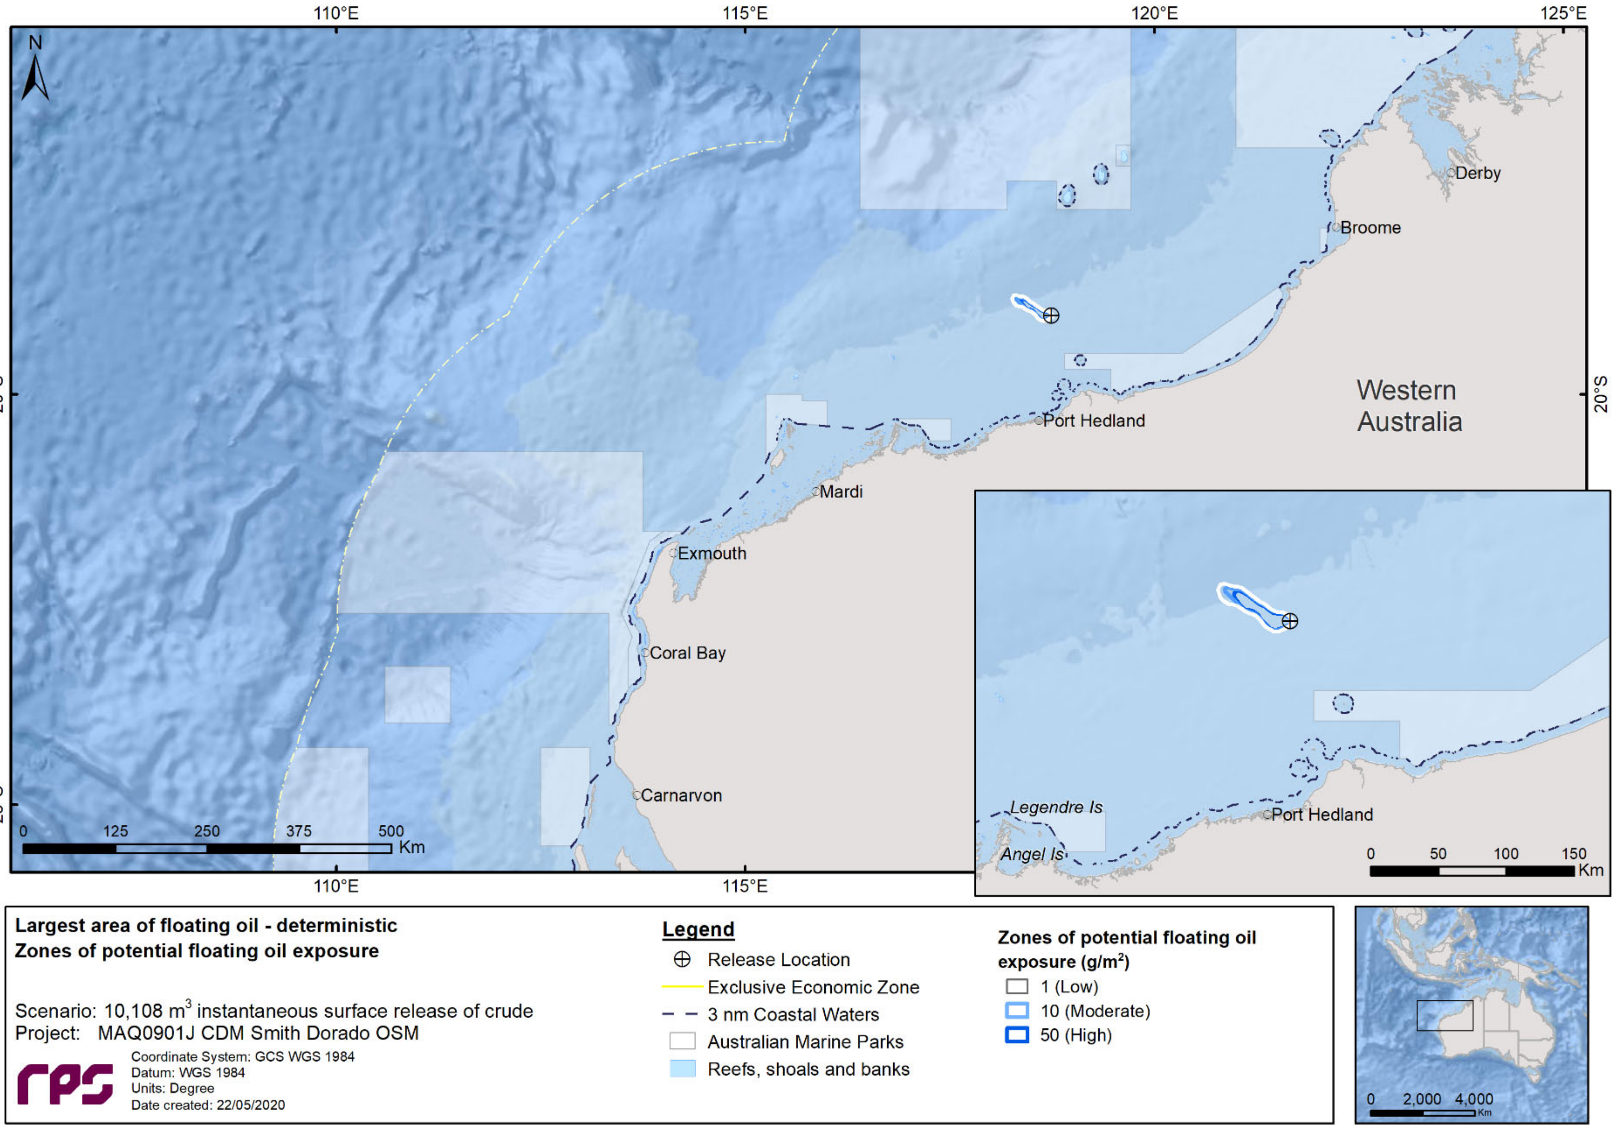

Figure 9.118 Exposure from floating oil (over the 42 day simulation) for the simulation with the largest area of floating oil above 50 g/m^2. Results are based on an instantaneous surface release of 10,108 m^3 of crude from the FPSO, starting 3 pm on the 26th of March 2017.

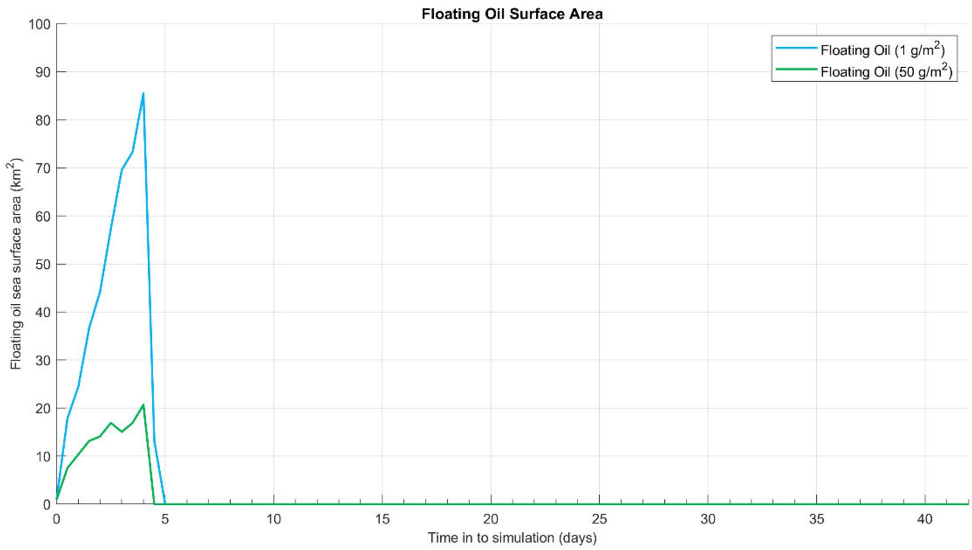

Figure 9.119 Time series of the area of visible (≥1 g/m^2) and actionable floating oil (≥50 g/m^2) on the sea surface for the simulation with the largest area of floating oil above 50 g/m^2. Results are based on an instantaneous surface release of 10,108 m^3 of crude from the FPSO, tracked for 42 days, 3 pm on the 26th of March 2017.

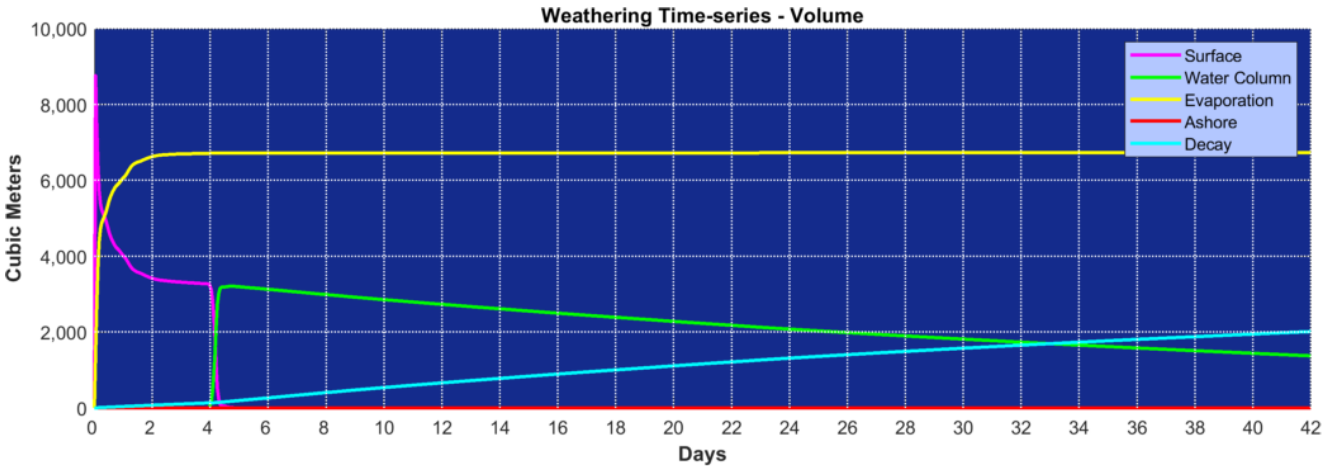

Figure 9.120 Predicted weathering and fates graph for the single spill simulation with the largest area of floating oil above 50 g/m^2. Results are based on an instantaneous surface release of 10,108 m^3 of crude from the FPSO, tracked for 42 days, 3 pm on the 26th of March 2017.

9.6.2.2 Deterministic Case: Largest Area of Entrained Hydrocarbons

The deterministic simulation that resulted in the largest area of entrained hydrocarbons was identified during winter conditions as run number 54, which commenced at 6 am on the 23rd of August 2018.

Exposure from floating oil over the entire 42 day simulation are presented in Figure 9.121. The exposure from floating oil was predicted to be within 19 km of the release location.

Figure 9.122 presents the predicted entrained hydrocarbon exposure zones in the 0-10 m depth layer for the entire simulation. Entrained hydrocarbons at the low threshold (10-100 ppb) were predicted to extend a maximum distance of approximately 1,010 km northwest from the release location and approximately 459 km northwest at the high threshold.

Figure 9.123 presents the predicted dissolved hydrocarbon exposure zones in the 0-10 m depth layer for the entire simulation. Dissolved hydrocarbons at the low threshold (10-50 ppb) were predicted to extend a maximum distance of approximately 984 km northwest from the release location and approximately 413 km northwest and 41 km west-northwest at the moderate (50 – 400 ppb) and high (≥400 ppb) thresholds, respectively.

Figure 9.124 presents the fates and weathering graph for the corresponding single spill simulation. At the conclusion of the simulation period, approximately 4,098 m^3 (41%) spilled oil was lost to the atmosphere through evaporation. Approximately 4,391 m^3 (43%) of the crude was predicted to have decayed, while approximately 1,619 m^3 (16%) was predicted to remain within the water column.

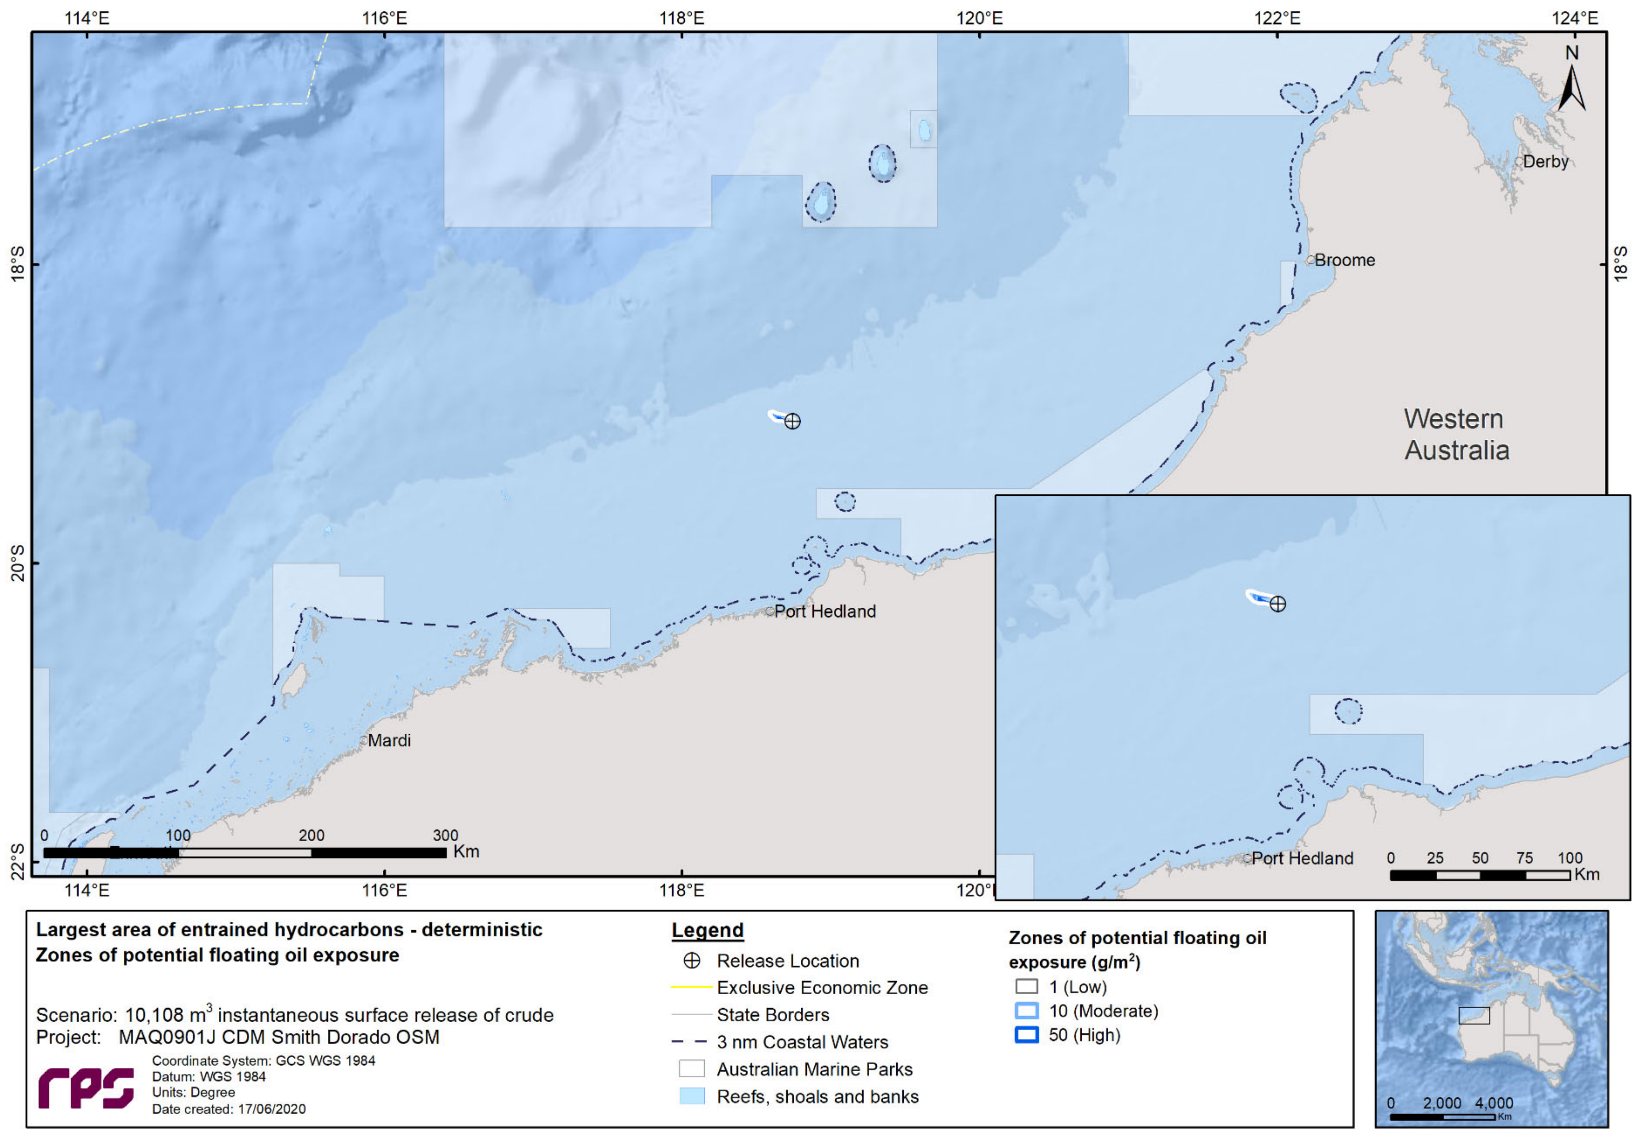

Figure 9.121 Exposure from floating oil (over the 42 day simulation) for the simulation with the largest area of entrained hydrocarbons. Results are based on an instantaneous surface release of 10,108 m³ of crude from the FPSO, starting 6 am on the 23rd of August 2018.

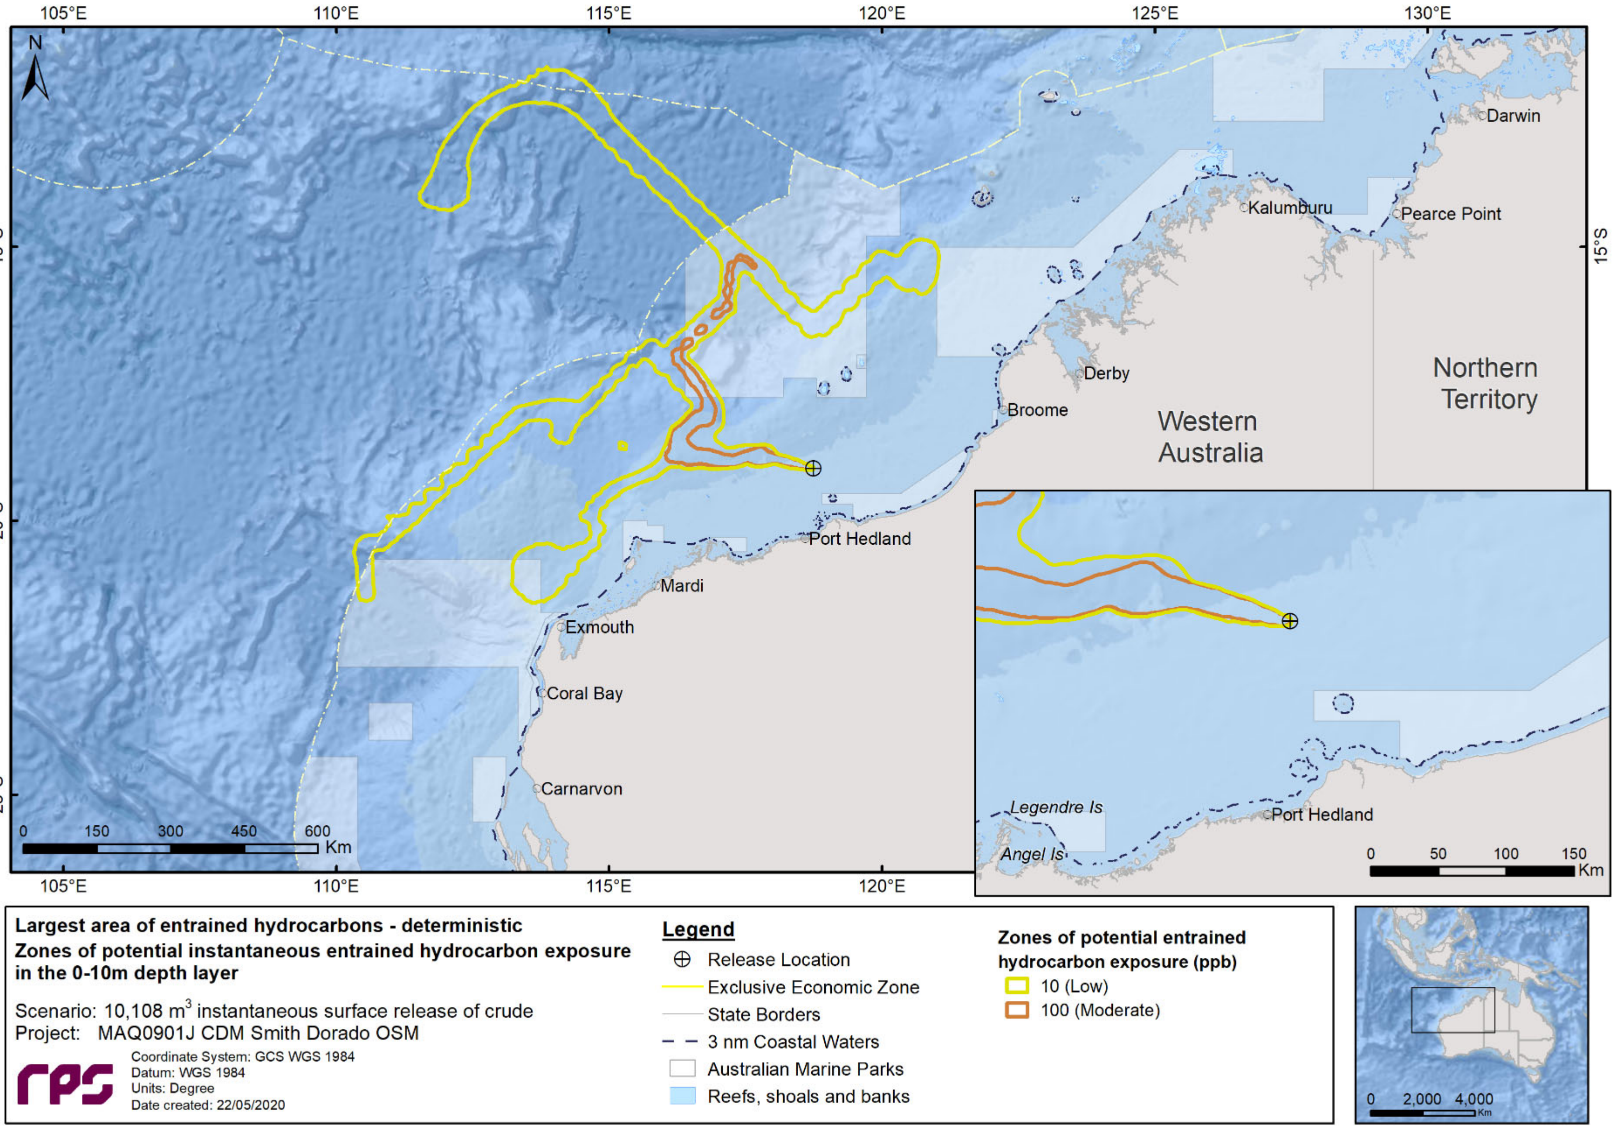

Figure 9.122 Predicted entrained hydrocarbon exposure zones in the 0-10 m depth layer for the simulation with the largest area of entrained hydrocarbons. Results are based on an instantaneous surface release of 10,108 m³ of crude from the FPSO, tracked for 42 days, 6 am on the 23rd of August 2018.

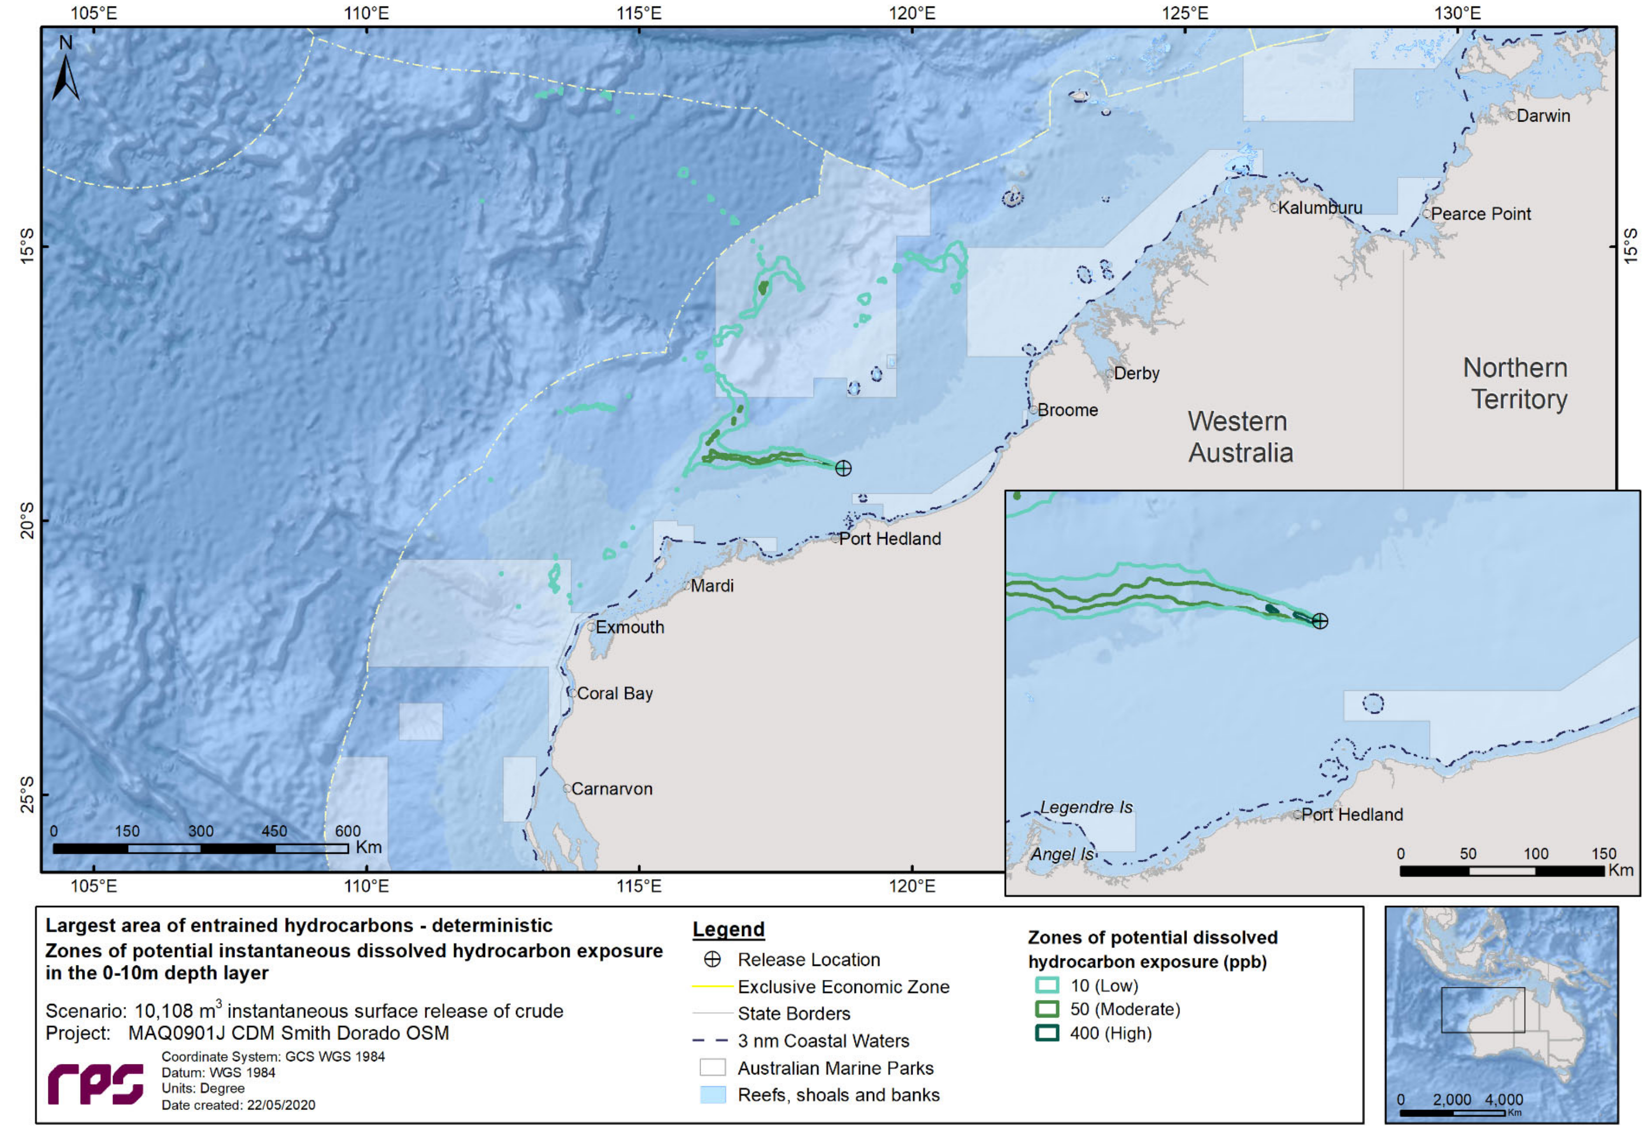

Figure 9.123 Zones of potential instantaneous dissolved hydrocarbon exposure in the 0-10 m depth layer for the simulation with the largest area of entrained hydrocarbons. Results are based on an instantaneous surface release of 10,108 m^3 of crude from the FPSO, tracked for 42 days, 6 am on the 23rd of August 2018.

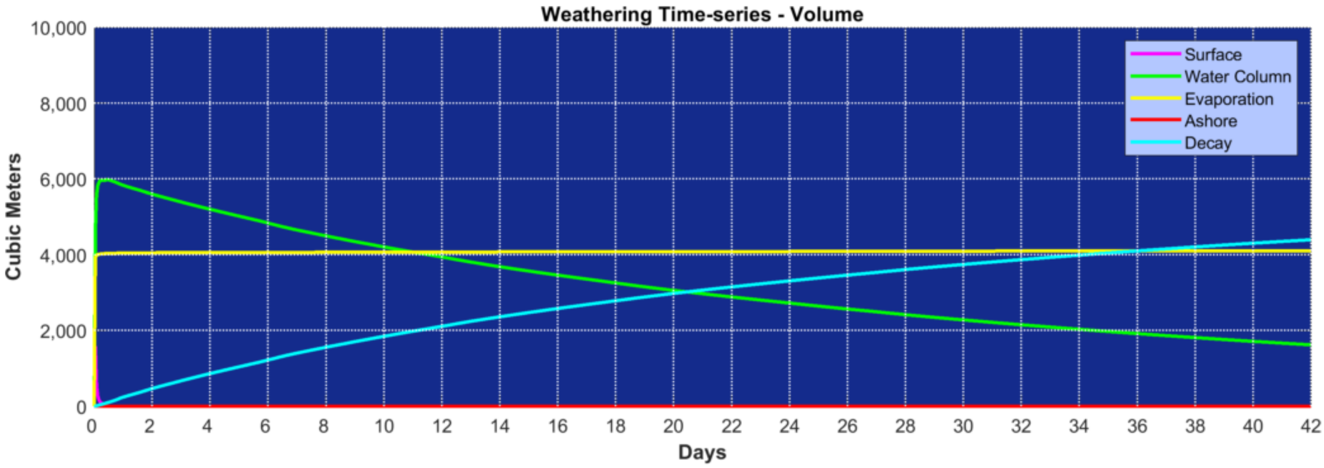

Figure 9.124 Predicted weathering and fates graph for the single spill simulation with the largest area of entrained hydrocarbons. Results are based on an instantaneous surface release of 10,108 m^3 of crude from the FPSO, tracked for 42 days, 6 am on the 23rd of August 2018.

9.6.3 Seasonal analysis

9.6.3.1 Floating Oil Exposure

Table 9.49 summarises the maximum distances from the release location to floating oil exposure zones for each season. The maximum distance from the release location to the low (1–10 g/m^2), moderate (10–50 g/m^2) and high (≥ 50 g/m^2) exposure thresholds was 361.3 km west, 152.3 km west-southwest and 151.5 km west-southwest, respectively, all during transitional conditions.

Images of floating oil exposure zones are depicted in Figure 9.125, Figure 9.126 and Figure 9.127 for the combined 100 spill simulations commencing during summer, transitional and winter conditions, respectively.

Table 9.50 to Table 9.52 summarise the potential floating oil exposure to individual sensitive receptors for each season. Exposure at the low threshold was predicted at 1 AMP (Mermaid Reef) during the summer season only with a probability of 1% and a time of exposure of 24.5 days.

Floating oil exposure at the low threshold was predicted at 2 RSBs (Clerke Reef and Mermaid Reef), only during summer conditions and the probability of exposure was 1% for both RSBs. The shortest time before exposure was predicted at Clerke Reef, taking 12.71 days.

Low (1-10 g/m^2) floating oil was only predicted to cross WA State Waters during summer with a probability of 1%. It took 12.71 days for the oil to cross into WA State Waters.

Table 9.49 Maximum distance and direction from the release location to floating oil exposure thresholds. Results are based on an instantaneous surface release of 10,108 m^3 of crude from the FPSO. The results were calculated from 100 spill simulations per season.

Season	Distance and direction	Exposure from floating oil		
		Low (1-10 g/m^2)	Moderate (10-50 g/m^2)	High (≥50 g/m^2)
Summer	Max. distance from release site (km)	326	50.5	43.3
	Max distance from release site (km) (99th percentile)	138.5	46.3	41.0
	Direction	West-Southwest	West-Northwest	West-Northwest
Transitional	Max. distance from release site (km)	361.3	152.3	151.5
	Max distance from release site (km) (99th percentile)	249.1	150.1	149.9
	Direction	West	West-Southwest	West-Southwest
Winter	Max. distance from release site (km)	163	48.1	39.5
	Max distance from release site (km) (99th percentile)	114.1	43.6	38.3
	Direction	Northwest	Northeast	West-Southwest

9.6.3.2 Shoreline Accumulation

There was no shoreline accumulation predicted for any spills during this scenario at, or above, the low threshold (≥10 g/m^2).

9.6.3.3 Entrained Hydrocarbons

Images of entrained hydrocarbon exposure in the 0-10 m depth layer are depicted in Figure 9.128, Figure 9.129 and Figure 9.130 for the combined 100 spills each commencing during summer, transitional and winter conditions, respectively. The seasonal results indicated that exposure at the low threshold was predicted to occur up to a maximum distance of 1,017 km (southwest) from the spill site during summer conditions. This distance reduced to 939 km (west-southwest) as the contact threshold increased to moderate (≥ 100 ppb) in summer conditions. The maximum distances for transitional and winter conditions at the low threshold were 999 km and 990 m, respectively. The maximum distances at the moderate threshold were reduced for transitional (973 km) and winter (754 km).

Table 9.53 to Table 9.55 summarise the probability of exposure to individual sensitive receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer for each season. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at their shallowest depth from the sea surface.

Ten AMPs are within the low exposure zone across the 3 seasons, with the Montebello AMP recording the highest probability of exposure of 20% during winter conditions. The shortest time for entrained hydrocarbons at the low threshold to reach an AMP was recorded at Dampier during transitional conditions as 3.13 days.

Glomar Shoals was the only KEF exposed to entrained hydrocarbons at the low threshold during all 3 seasons with the probability varying from 21 to 24%. The Commonwealth waters adjacent to Ningaloo Reef KEF was the only other receptor exposed to entrained hydrocarbons at the low threshold during transitional conditions only (1% probability).

Twelve RSB are within the low exposure zone across the three seasons, with the greatest probability of exposure predicted at Ranking Bank during winter conditions (24%). The quickest time before exposure at the low threshold to an RSB receptor was predicted at Montebello Shoals, 7.9 days during winter conditions.

Entrained hydrocarbons at the low threshold were predicted to cross WA State Waters during all 3 seasons, with probabilities ranging from 8% (summer) to 15% (winter). The minimum time before oil crossed the WA State Waters boundary was 4.58 days, recorded during transitional conditions.

Table 9.53 Probability of exposure to individual receptors from instantaneous entrained hydrocarbons in the 0-10 m depth layer. Results are based on an instantaneous surface release of 10,108 m^3 of crude from the FPSO during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of entrained hydrocarbon exposure		Minimum time (days) before hydrocarbon exposure at any depth		Maximum entrained hydrocarbon concentration (ppb)

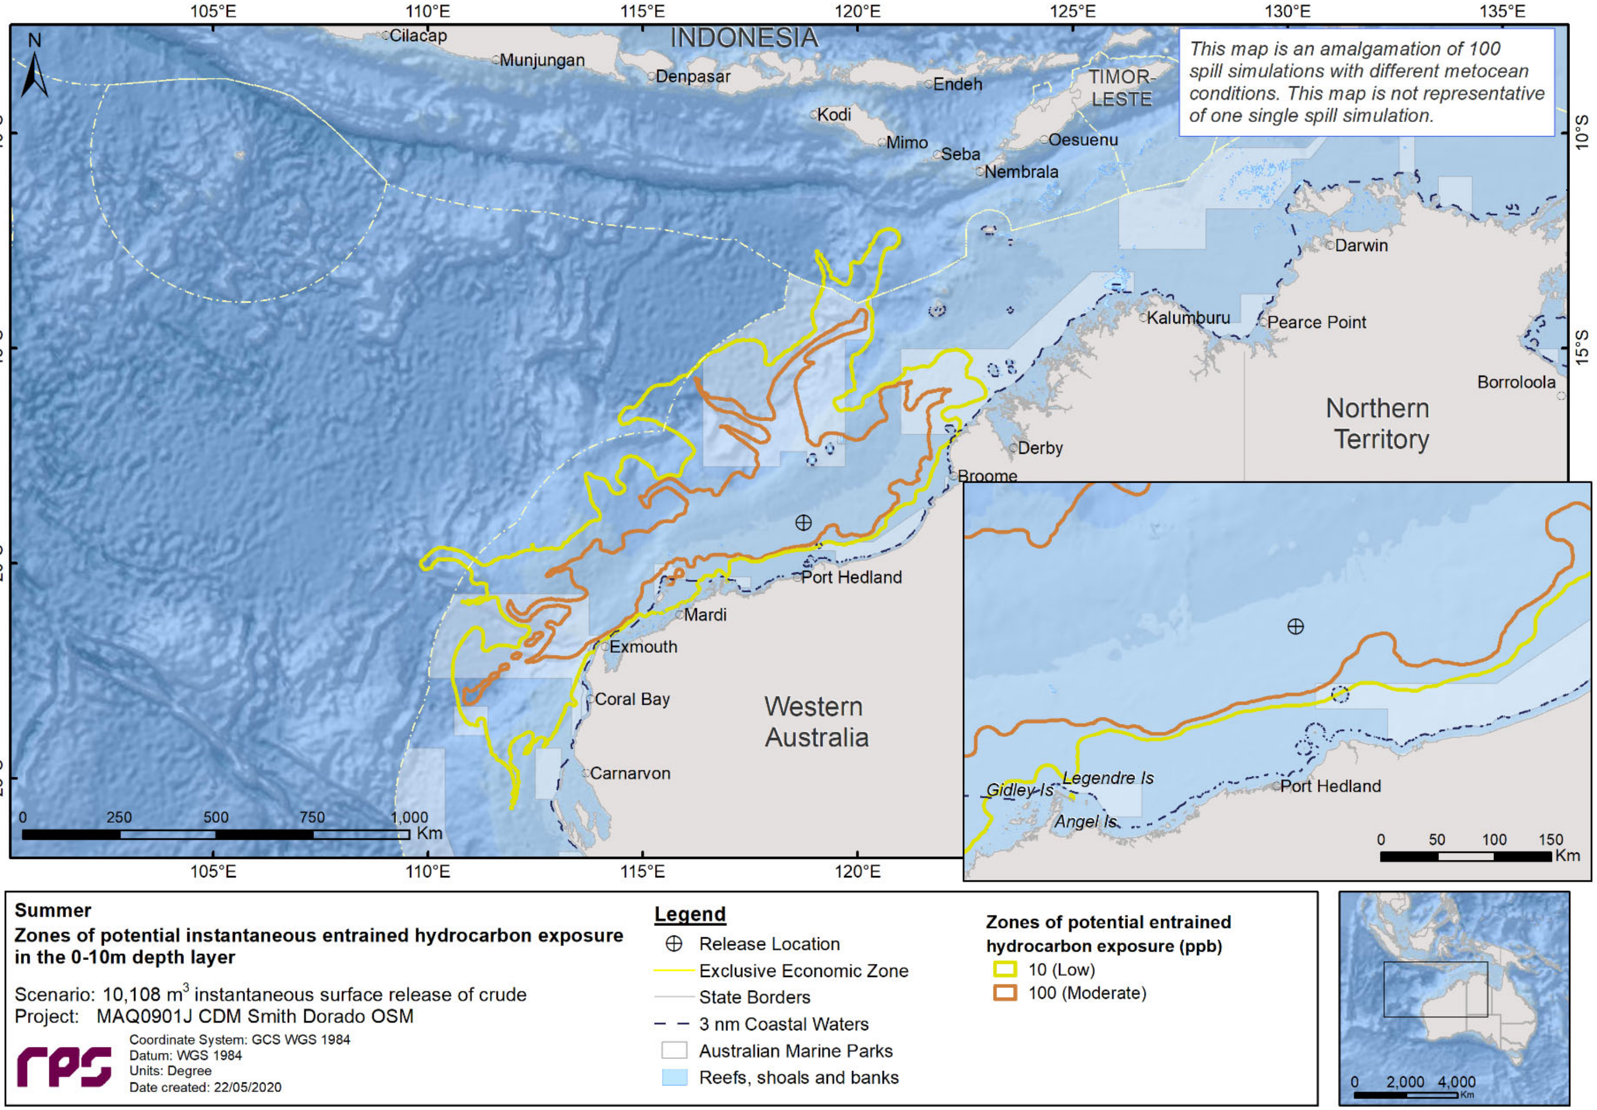

Figure 9.128 Predicted entrained hydrocarbon exposure zones resulting from an instantaneous surface release of 10,108 m^3 of crude from the FPSO. The results were calculated from 100 spill simulations commencing during summer (October to March) conditions.

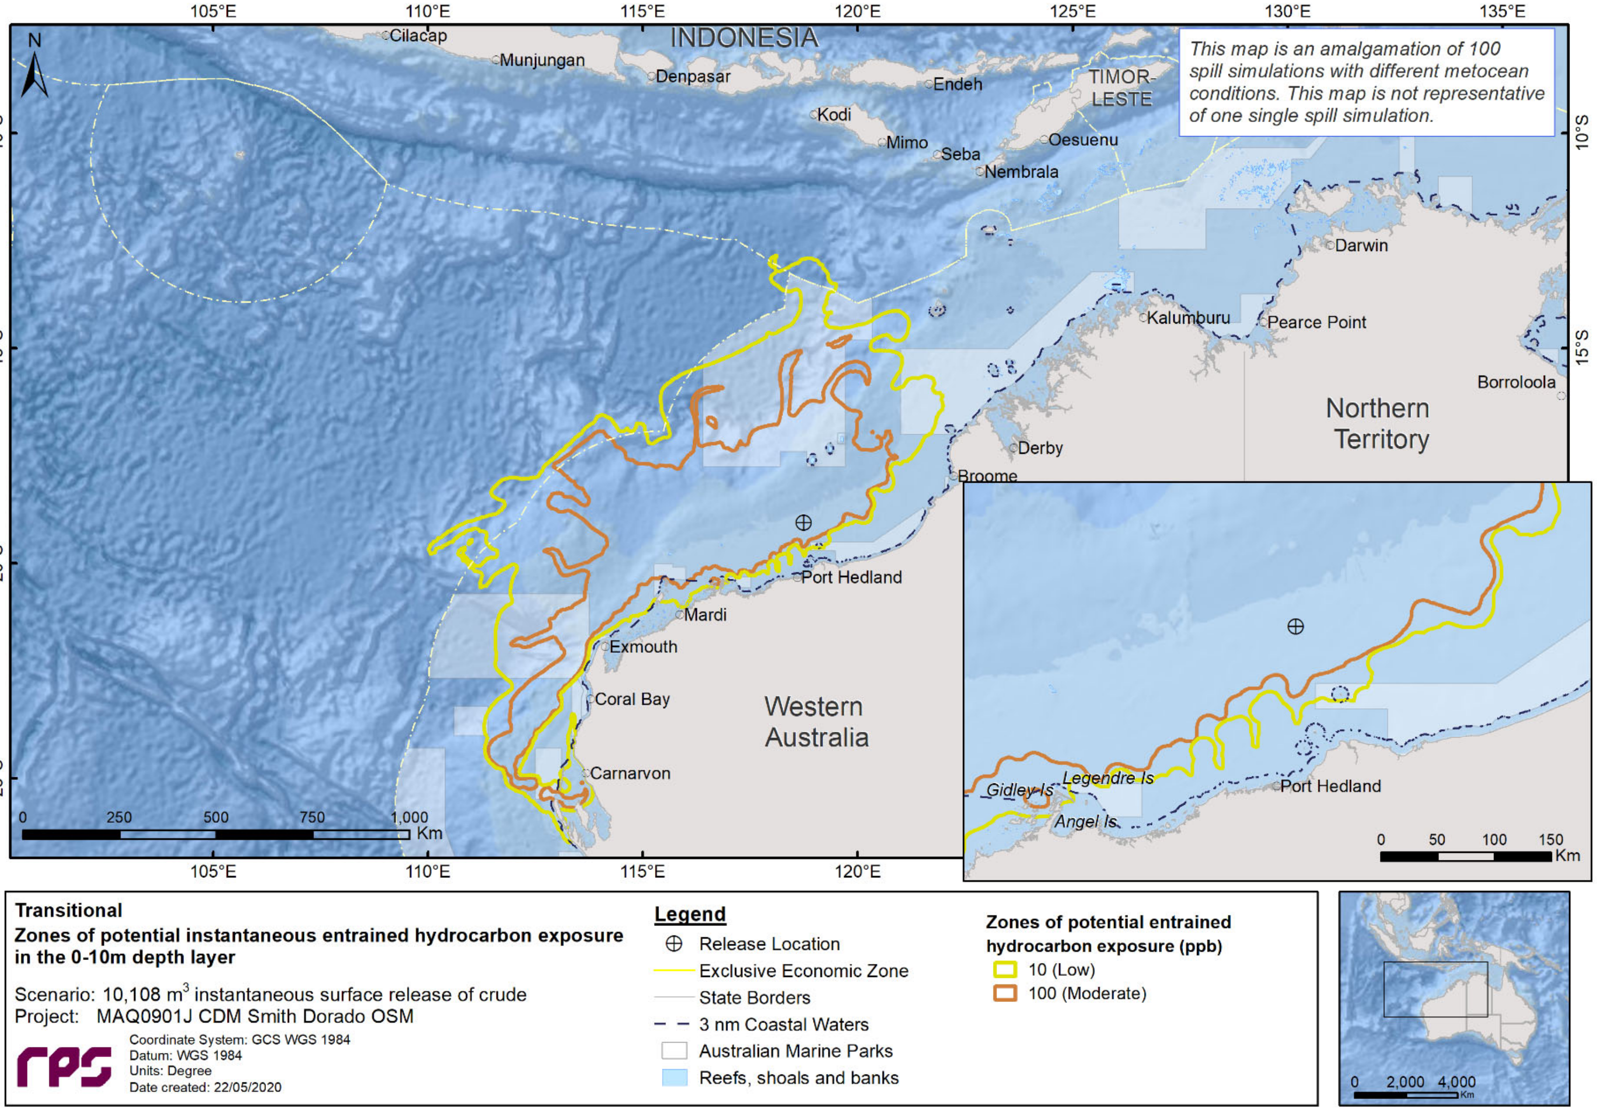

Figure 9.129 Predicted entrained hydrocarbon exposure zones resulting from an instantaneous surface release of 10,108 m^3 of crude from the FPSO. The results were calculated from 100 spill simulations commencing during transitional (April and September) conditions.

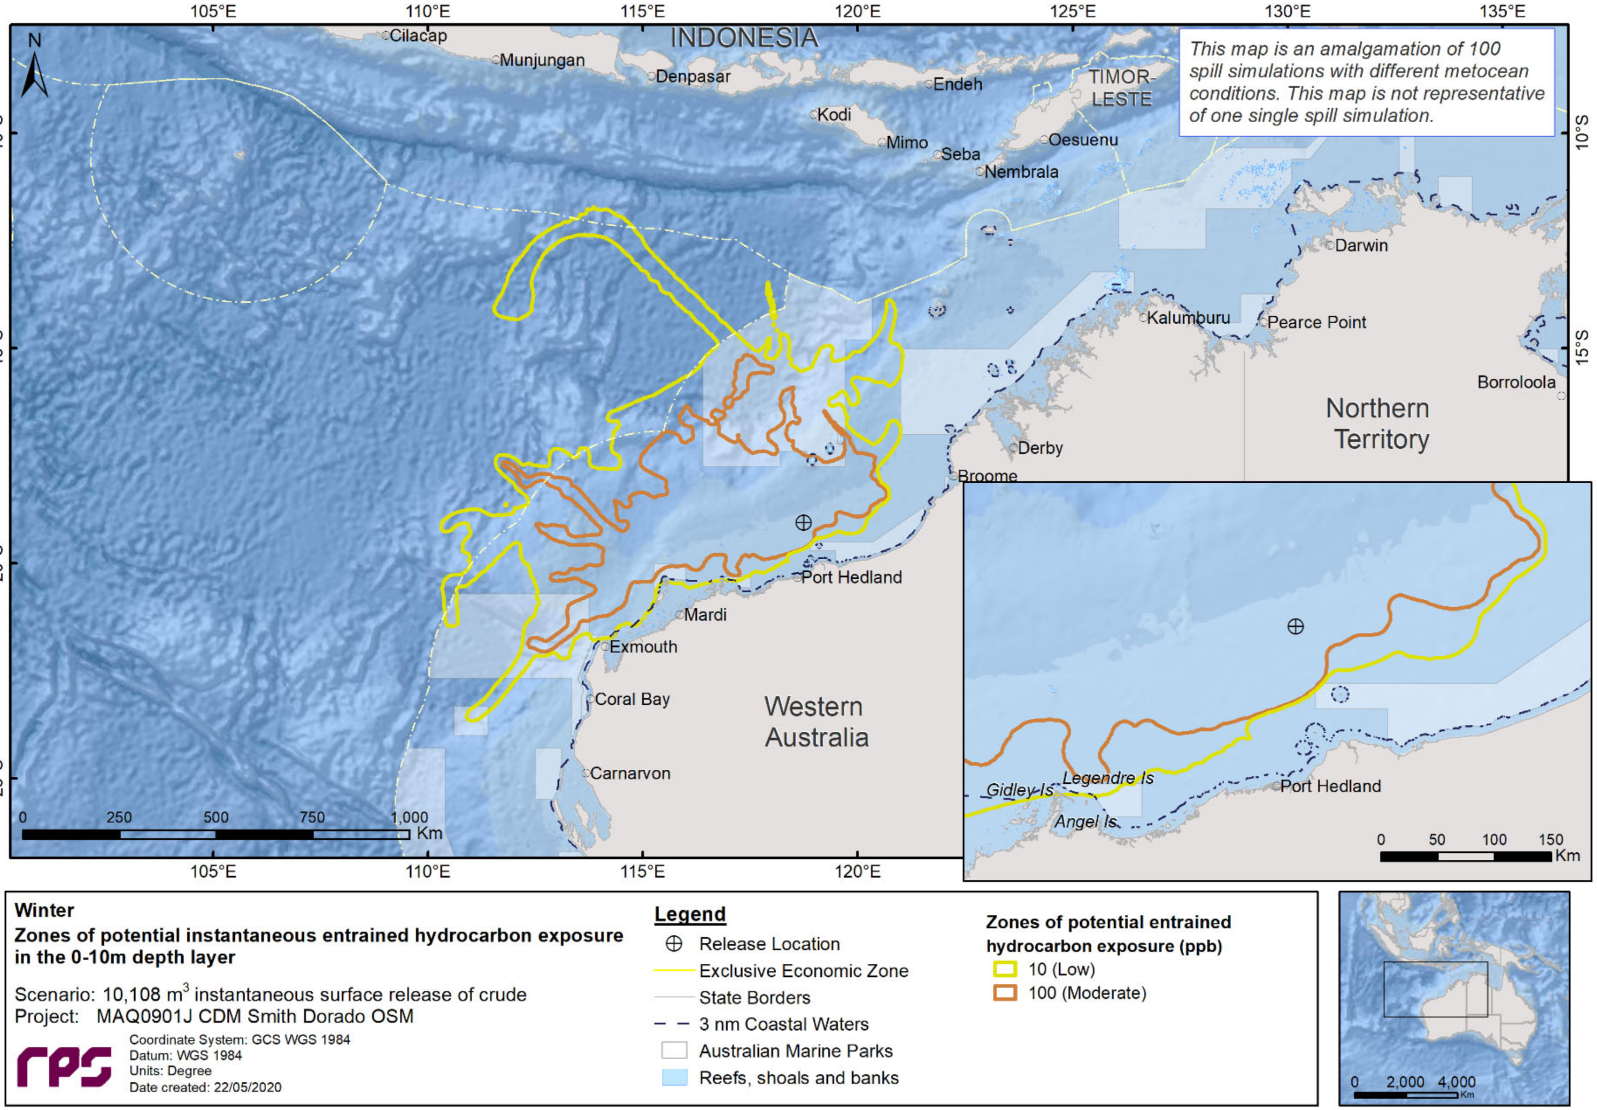

Figure 9.130 Predicted entrained hydrocarbon exposure zones resulting from an instantaneous surface release of 10,108 m^3 of crude from the FPSO. The results were calculated from 100 spill simulations commencing during winter (May to August) conditions.

9.6.3.4 Dissolved Hydrocarbons

Images of dissolved hydrocarbon exposure zones are depicted in Figure 9.131, Figure 9.132 and Figure 9.133 for the combined 100 spill simulations each commencing during summer, transitional and winter conditions, respectively. The maximum distance from the spill site to the low exposure threshold (10-50 ppb) for summer, transitional and winter results were 940 km (west-southwest), 978 km (southwest) and 967 km (northwest), respectively. This distance reduced to 564 km (north northeast; summer), 931 km (southwest; transitional) and 573 km (west; winter) as the threshold increased to moderate (50 – 400 ppb). Based on the high threshold (≥400 ppb) the distance reduced further to 45 km (west southwest; summer), 58 km (west; transitional) and 88 km (west southwest; winter).

Table 9.56 to Table 9.58 summarise the probability of exposure to receptors from instantaneous dissolved hydrocarbons in the 0-10 m depth layer, for each season. Note the probability and maximum concentrations for the KEFs and Glomar Shoals RSB were individually assessed at their shallowest depth from the sea surface.

Across the 3 seasons, 10 AMPs are within the low exposure zone, with Argo-Rowley Terrace AMP recording the highest probability of exposure of 7% during transitional conditions. Dampier AMP was predicted to be exposed quickest at 4.13 days during transitional conditions. Glomar Shoals was the only KEF to be exposed by dissolved hydrocarbons at the low threshold with probabilities between 1 – 6%.

Five RSB are within the low exposure zone across the three seasons, with the highest probability predicted at Clerke Reef during transitional conditions (6%). The minimum time before exposure at an RSB receptor was 7.9 days at Rankin Bank during transitional conditions.

Dissolved hydrocarbons at the low threshold were predicted to cross WA State Waters during every season with probabilities ranging from 3-7%. The minimum time before oil crossed the WA State Waters boundary was 4.63 days during transitional conditions.

Table 9.56 Probability of exposure to individual receptors from instantaneous dissolved hydrocarbons in the 0-10 m depth layer. Results are based on an instantaneous surface release of 10,108 m^3 of crude from the FPSO during summer (October to March) conditions. The results were calculated from 100 spill simulations.

Receptors		Probability (%) of dissolved hydrocarbon exposure			Minimum time (days) before hydrocarbon exposure at any depth			Maximum dissolved hydrocarbon concentration (ppb)

Executive summary

Oil spill modelling was undertaken to predict the potential environmental impacts from four hypothetical Loss Of Well Control (LOWC) incidents related to the proposed Bedout Basin multi-well exploration drilling by Santos WA Energy Ltd (Santos). Santos defined four LOWC scenarios for assessment as follows:

– A LOWC at the Apus well location with the release of 10,982,250 STB (1,745,986 m^3) and 19,255 MMscf (545.25 million sm^3) gas at the seabed (Apus Base Case Subsea LOWC)
– A LOWC at the Apus well location with the release of 10,858,774 STB (1,746,355 m^3) and 19,039 MMscf (539.12 million sm^3) gas at the sea surface (Apus Base Case Surface LOWC)
– A LOWC from an alternate well design at the Apus well location with the release of 8,964,764 STB (1,425,241 m^3) and 15,718 MMscf (445.01 million sm^3) gas at the seabed (Apus Alternate Subsea LOWC)
– A LOWC from an alternate well design at the Apus well location with the release of 8,377,354 STB (1,331,852 m^3) and 14,688 MMscf (415.92 million sm^3) gas at the sea surface (Apus Alternate Surface LOWC)

Oil spill modelling was carried out with SINTEF's Oil Spill Contingency and Response (OSCAR) system. Modelling was undertaken in stochastic mode (total of 150 realisations per scenario) with start dates spaced approximately fortnightly over a five (5) year period. Inputs into the model were sourced from HYCOM (regional ocean currents, temperature and salinity profiles), TPXO9 (tidal currents) and CFSv2 (regional winds). Deterministic modelling was also carried out on several simulations to further characterise impacts and to inform response planning.

Analysis of the stochastic simulations was based on the following moderate thresholds:

– Accumulated shoreline oiling above 100 g/m^2.
– Surface hydrocarbons above 10 g/m^2.
– Total submerged oil (a combination of entrained + dissolved oil) above 100 ppb.
– Dissolved hydrocarbons above 50 ppb.

Additional interrogation of the modelling predictions also considered the following low and high thresholds:

– Accumulated shoreline oiling above 10 g/m^2 (low) and 1,000 g/m^2 (high).
– Surface hydrocarbons above 1 g/m^2 (low) and 50 g/m^2 (high).
– Total submerged oil (a combination of entrained and dissolved oil) above 10 ppb (low).
– Dissolved hydrocarbons above 10 ppb (low) and 400 ppb (high).

An overview of the shoreline loading predictions above the moderate threshold (100 g/m^2) from the scenarios includes the following:

– **Apus Base Case Subsea LOWC:** a 100% contact probability is predicted with a maximum accumulated shoreline load of 2,054 tonnes, a minimum arrival time of 3.5 days and a maximum length of oiled shoreline of 433 km.
– **Apus Base Case Surface LOWC:** a 100% contact probability is predicted with a maximum accumulated shoreline load of 5,125 tonnes, a minimum arrival time of 2.0 days and a maximum length of oiled shoreline of 500 km.
– **Apus Alternate Subsea LOWC:** a 100% contact probability is predicted with a maximum accumulated shoreline load of 984 tonnes, a minimum arrival time of 5.8 days and a maximum length of oiled shoreline of 318 km.
– **Apus Alternate Surface LOWC:** a 100% contact probability is predicted with a maximum accumulated shoreline load of 3,573 tonnes, a minimum arrival time of 2.0 days and a maximum length of oiled shoreline of 404 km.

Deterministic simulations of dispersant response strategies of the base case LOWC scenarios via subsea dispersant injection (SSDI) and surface dispersant application (SDA) predicted the following outcomes:

- SSDI of the subsea LOWC scenario generally had a negligible benefit. The high exit velocity of the subsea plumes from the well for these scenarios results in small, entrained oil droplets that are not materially affected by the application of chemical dispersants.
- The simulated SDA responses that were included for both subsea and surface LOWC scenarios generally had a greater benefit in reducing surface oil loads (via increased proportion of entrained oil with very small particle diameters) in comparison to the SSDI responses.
- SDA is predicted to generally provide moderate to significant reductions in shoreline loading.
- The incorporation of a 25 km radius exclusion zone around the well site (inside which no dispersants are applied) is effective in allowing a significant degree of natural evaporation to occur prior to treatment of the surface slick with chemical dispersant.
- The simulated maximum volume of chemical dispersant for any of the deterministic scenarios was 26,453 m^3 for the Apus Base Case Subsea Scenario #24, which results from the combined application of 15.587 m^3 via SSDI and 10,886 m^3 via SDA.

This report is subject to, and must be read in conjunction with, the limitations set out in section 1.3 and the assumptions and qualifications contained throughout the Report.

1. Introduction

1.1 Background

Santos WA Energy Ltd (Santos) proposes to undertake multi-well exploration drilling activities (the activity) within the Bedout Basin, located in Commonwealth waters north of Port Hedland.

To proceed with the activity, Santos is required to submit an Environment Plan (EP) and Oil Pollution Emergency Plan (OPEP) for approval by NOPSEMA for the Bedout Basin Multi-Well Exploration Drilling activity. The EP will describe the potential environmental impacts and risks related to the activity, while the OPEP will outline the Santos approach to respond to potential oil pollution incidents.

Santos has identified a loss of well control (LOWC) as the worst-case type of credible oil release scenario that could potentially occur during the activity. A LOWC incident may discharge directly to the sea surface or at the seabed, depending on the type of failure that occurs.

Santos has submitted an EP for the activity to NOPSEMA (Santos, 2021), and is currently in the process of updating the EP to address NOPSEMA comments. Part of these updates include the previous LOWC oil spill modelling by GHD (2021) for surface and subsea LOWC scenarios at three (3) locations that spanned the proposed operational area for the exploration drilling campaign (at the time of the GHD [2021]). Santos has narrowed down the worst-case scenarios for assessment since the previous (GHD, 2021) modelling. The worst-case scenarios are based on LOWC events occurring at the Apus well location, which is the closest of the proposed wells to the receptors of Bedout Island and the Australian mainland. Surface and subsea LOWC scenarios are defined for two well designs; a base case and an alternate well design that results in reduced flow rates of oil and gas during a hypothetical LOWC incident. The worst-case discharge scenarios defined by Santos adopt simulated flow rates from the Pavo well and apply them to the Apus location. The Pavo and Apus well locations are displayed in Figure 1.

1.2 Purpose of this report

Santos engaged GHD Pty Ltd (GHD) to perform oil spill modelling for the updated worst-case LOWC incidents related to the Bedout Basin Multi-Well Exploration Drilling activity to inform preparation of the updated EP and OPEP. This report details the oil spill modelling methodology, model inputs and simulated results of four LOWC scenarios.

1.3 Scope and limitations

The following worst-case credible oil spill scenarios were assessed:

- A LOWC at the Apus well location with the release of 10,982,250 STB (1,745,986 m^3) and 19,255 MMscf (545.25 million sm^3) gas at the seabed (Apus Base Case Subsea LOWC)
- A LOWC at the Apus well location with the release of 10,858,774 STB (1,746,355 m^3) and 19,039 MMscf (539.12 million sm^3) gas at the sea surface (Apus Base Case Surface LOWC)
- A LOWC from an alternate well design at the Apus well location with the release of 8,964,764 STB (1,425,241 m^3) and 15,718 MMscf (445.01 million sm^3) gas at the seabed (Apus Alternate Subsea LOWC)
- A LOWC from an alternate well design at the Apus well location with the release of 8,377,354 STB (1,331,852 m^3) and 14,688 MMscf (415.92 million sm^3) gas at the sea surface (Apus Alternate Surface LOWC)

The spill scenarios were modelled in stochastic mode with 150 replicate simulations (or realisations) to spatially define the Environment that May Be Affected (EMBA) on a probabilistic basis to inform development of the EP. Deterministic modelling was also carried out for selected worst-case realisations of the base case scenarios to further characterise impacts and to inform response planning of the OPEP. Additional deterministic modelling was applied to predict the impact of surface and subsea dispersant response strategies on mitigating oil spill impacts.

This report: has been prepared by GHD for Santos WA Energy Limited and may only be used and relied on by Santos WA Energy Limited for the purpose agreed between GHD and Santos WA Energy Limited as set out in section 1.2 of this report.

GHD otherwise disclaims responsibility to any person other than Santos WA Energy Limited arising in connection with this report. GHD also excludes implied warranties and conditions, to the extent legally permissible.

The services undertaken by GHD in connection with preparing this report were limited to those specifically detailed in the report and are subject to the scope limitations set out in the report.

The opinions, conclusions and any recommendations in this report are based on conditions encountered and information reviewed at the date of preparation of the report. GHD has no responsibility or obligation to update this report to account for events or changes occurring subsequent to the date that the report was prepared.

The opinions, conclusions and any recommendations in this report are based on assumptions made by GHD described in this report. GHD disclaims liability arising from any of the assumptions being incorrect.

GHD has prepared this report on the basis of information provided by Santos WA Energy Limited and others who provided information to GHD (including Government authorities), which GHD has not independently verified or checked beyond the agreed scope of work. GHD does not accept liability in connection with such unverified information, including errors and omissions in the report which were caused by errors or omissions in that information.

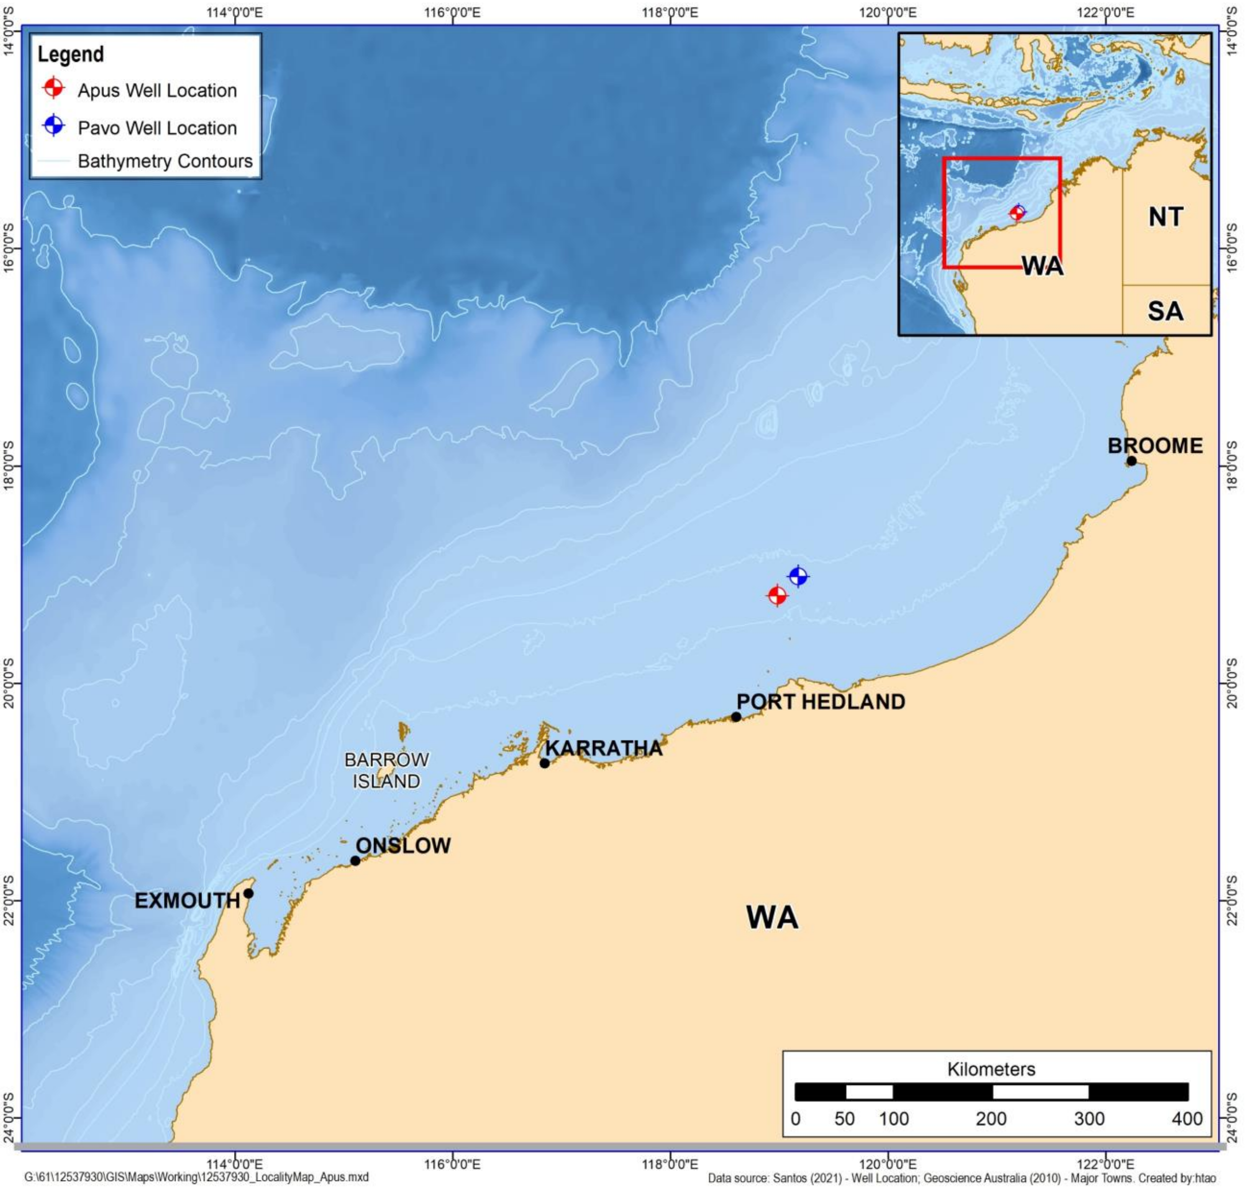

Figure 1 Locality Map

2. Data

2.1 Release Specifications

Time series of liquid condensate, gas and water release rates of the four (4) LOWC scenarios are presented in Table 1-Table 4, respectively. The general spill specifications for the LOWC scenarios are summarised in Table 5.

Table 1 Apus Base Case Subsea LOWC scenario release rates

Time	Condensate Rate (STB/d)	Gas Rate (MMscf/d)	Water Rate (STB/d) [1]
Week 1	147,517	259	-
Week 2	145,390	255	0
Week 3	144,171	253	0
Week 4	143,295	251	1
Week 5	142,607	250	3
Week 6	142,038	249	7

Table 5 Summary of spill specifications for the four LOWC scenarios

Parameter	Apus Base Case Subsea LOWC	Apus Base Case Surface LOWC	Apus Alternate Subsea LOWC	Apus Alternate Surface LOWC
Location (Lat, Lon)	19° 11' 25.29" S 118° 59' 10.64" E			
Hydrocarbon type	Caley			
Depth of spill (m)	72.6	0 (Surface spill)	72.6	0 (Surface spill)
Diameter of subsea release orifice (m)	0.30	NA	0.21	NA
Liquid release volume	10,982,250 STB ($1,745,986\ m^3$)	10,858,774 STB ($1,746,355\ m^3$)	8,964,764 STB ($1,425,241\ m^3$)	8,377,354 STB ($1,331,852\ m^3$)
Gas release volume	19,255 MMscf (545.25 million sm^3)	19,039 MMscf (539.12 million sm^3)	15,718 MMscf (445.01 million sm^3)	14,688 MMscf (415.92 million sm^3)
Release duration	77 days			
Timing of release risk period	All year			

2.2 Hydrocarbon Specifications

2.2.1 LOWC Hydrocarbon– Caley

The hydrocarbon type for the LOWC scenarios was identified by Santos as Caley (named 'Caley Crude' in Intertek [2020], however Intertek [2020] also refers to the oil as a condensate and the hydrocarbon properties are representative of those of condensates). An assay report (Intertek, 2020) with information on the physical and chemical properties of the condensate were provided by Santos. Key physical/chemical properties of Caley from the assay report are shown in Table 6.

Table 6 Bulk properties of Caley from Intertek (2020)

Parameter	Caley (Intertek, 2020)
API Gravity	51.4
Specific Gravity	0.7737
Wax Content (%)	9.2
Pour Point (°C)	<-15
Asphaltene (%)	<0.5
Viscosity (cSt)	1.878 (@20°C)

2.3 Environmental Data

The environmental inputs for oil spill modelling include regional ocean currents, winds, and seawater temperatures and salinities.

2.3.1 Ocean Currents

Currents in the Indian Ocean are dominated by two rotating gyres. The larger gyre is located in the southern hemisphere, rotates counter-clockwise, and is driven by Trade Winds and Mid-Latitude Westerlies. The eastern arm of this gyre, the Western Australian Current (WAC), flows northward off the continent's west coast, bending counter-clockwise to form the South Equatorial Current (SEC), which flows toward Mozambique (Schott and McCreary 2001; Shankar *et al*., 2002).

The gyre in the Northern Indian Ocean is driven predominantly by the Indo-Australian Monsoon winds, and as such is much more seasonally variable than the subtropical gyre to the south. During the Australian Winter the gyre rotates clockwise, while in summer it rotates counter-clockwise (Shankar *et al*., 2002).

Semi-diurnal tidal currents are extremely strong. The dominant tidal components, M2 and S2, are magnified on the shelf, resulting in one of the largest tidal ranges of any open coastline in the world. Tidal ranges can be as high as 6 m off the Pilbara coast and 10 m off the Kimberley coast. This can result in currents of up to 1 m/s. During tropical cyclones surface currents may reach 4 m/s (Chang *et al*., 2016).

Large-scale oceanographic and tidal currents are sourced from the global ocean circulation model HYCOM (Chassignet *et al*., 2007) and the global tide model TPXO9 (Egbert & Erofeeva, 2002), respectively. The HYCOM and TPXO9 data span 1 January 2011 to 31 December 2015. The eight primary tidal constituents in TPXO9 were utilised in this study.

The spatial resolution of the HYCOM data is 1/12 of a degree of latitude/longitude (or approximately 9 km). The TPXO9 tidal current data were combined additively to the HYCOM data.

Monthly depth-averaged current roses generated from the HYCOM data, as well as the combined HYCOM and TPXO9 data are presented in Figure 2 and Figure 3 for the HYCOM node nearest to the simulated release location of the Apus well. Non-tidal currents are typically <5-25 cm/s and display some seasonality with:

– Westerly/south-westerly currents prevailing from April to July
– North-easterly currents prevailing from January to February

– A mixture of the regimes (south-westerly and north-westerly) during the remaining months of the year.

The inclusion of tidal currents typically results in a south-easterly/north-westerly oscillating pattern all year round with typical current speeds of 5-65 cm/s.

2.3.1.1 Adopting the Apus Well as the Worst-Case Location

Of the wells assessed by Santos for this multi-well exploration activity, the worst-case discharge rates during a LOWC incident are predicted to occur at the Pavo well (Figure 1). Despite this, Santos has defined a LOWC event at the Apus well to represent the worst-case scenario in terms of potential environmental impacts. The adoption of Apus as the worst-case location is justified as follows:

- The Apus-1 and Pavo-1 wells are 28 km apart and are in 72 m and 83 m water depths, respectively
- Apus-1 is the closest well to the nearest sensitive receptor (Bedout Island) at 46 km distance compared to Pavo-1 at 64 km distance. Further, Apus-1 is nearer to the mainland at 87 km compared to Pavo-1 at 104 km.
- The fluid for both wells is based on the same oil characteristics (Caley)
- Due to their proximity, the geometry of the Bedout Basin and gentle sloping water depth, the prevailing met-ocean conditions are likely to be very similar. Monthly currents roses at Apus (Figure 3) and Pavo (Figure 4) compare very closely.
- The size of the EMBA is primarily defined on the basis of entrained oil that is predicted to encompass a very large area (>1,500 km, see Section 4). Therefore the predicted EMBAs from LOWC incidents at these two proximal well locations would be similar as the distance between the wells is negligible relative to the overall scale potential impacts.
- Since the Pavo-1 well yields the worst case predicted discharge rates oil and gas during a LOWC incident, these flow rates serve as the model inputs at the Apus-1 well location.
- The application of worst-case discharge estimates of Pavo-1 at the Apus-1 well location is a conservative approach to characterise potential environmental risks associated with the multi-well drilling campaign.

2.3.2 Winds

Sea surface wind velocity fields were sourced from the National Centers for Environmental Prediction's (NCEP's) Climate Forecast System, version 2 (CFSv2) (Suranjana *et al.* 2014), spanning 1 January 2011 to 31 December 2015. The CFSv2 data is provided at hourly temporal resolution and 0.2 degree latitudinal/longitudinal resolution (approximately 22 km). Average monthly wind directions and wind speeds for each year of the 5-year dataset are shown in Figure 5 for the CFSv2 node nearest to the simulated release location. Monthly wind roses are presented in Figure 6. Monthly wind directions display a marked seasonal pattern with:

– April to August characterised by easterly/south-easterly winds
– South-westerly to north-westerly winds generally prevail from October to February
– March and September are transitional periods with a mixture of the two regimes.

Monthly-averaged wind speeds are typically higher (6-8 m/s) during the winter months of May to July, lower from September to March (2-5 m/s) and intermediate (2-6 m/s) at other times of year (Figure 5).

2.3.3 Temperature and Salinity Profiles

Temperature and salinity profiles are defined from the same five-year HYCOM dataset as the regional ocean currents (January 2011–December 2015). Vertical profiles of temperature and salinity were extracted from a HYCOM node near to the simulated release site. A single representative temperature and salinity profile of the average yearly conditions was applied across the entire model domain that provided the closest match (by least-squares regression) to the average density profile over the 5 years of HYCOM data. The selected salinity, temperature and density profile was 25 October 2011, shown on Figure 7.

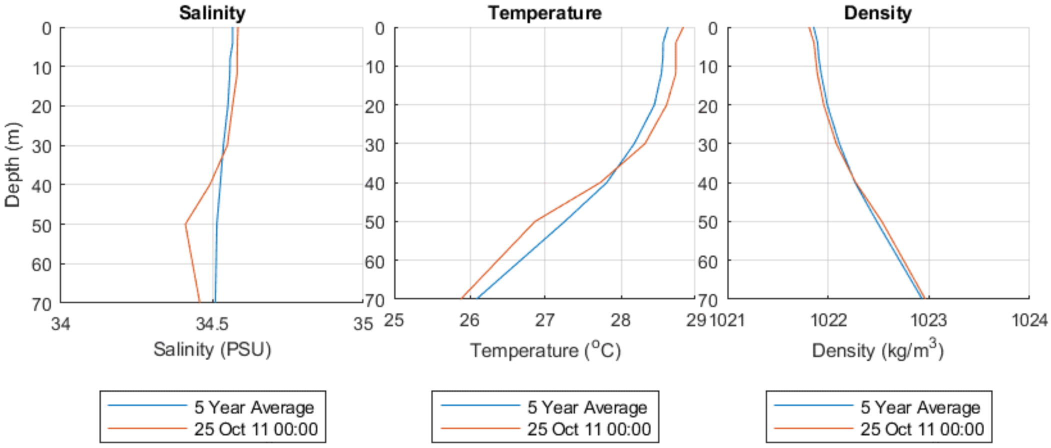

Figure 7 ***Selected salinity, temperature and density vertical profile and comparison with the yearly averages near the release site***

2.3.4 Environmental Receptors

To characterise the consequence of the simulated scenarios, discrete environmental receptors were defined by Santos, which are listed in Table 7 and displayed Figure 8 to Figure 10. The receptor regions have been allocated a sensitivity score by Santos to reflect the level of environmental value, where a higher score indicates greater sensitivity and/or value of the geographic receptor (Table 7).

Some receptors include reef systems, such as the Rowley Shoals of Clerke Reef Marine Park (Clerke Reef MP) and Imperieuse Reef MP, which are intertidal features that may only be exposed at low tides. In these instances, the large intertidal reef is classified as exposed shoreline during the model setup, which is a conservative measure to account for any potential oil stranding that might occur at these environmentally sensitive receptors. The length of 'shoreline' oiled for these receptors likely exceeds the actual length of permanently exposed shore within these receptor boundaries, as the statistic also includes the significantly larger reef in the classification of 'shoreline'.

3. Methodology

3.1 Description of the Model

Oil spill modelling was carried out with SINTEF's Oil Spill Contingency and Response (OSCAR) system (version 12.0). OSCAR is a system of integrated models that quantitatively assess the fate and transport of hydrocarbons in the marine environment, as well as evaluate the efficacy of response measures (Reed *et al*., 2001; Reed *et a*l., 2004). OSCAR provides an integrated hydrocarbon transport and weathering model that accounts for hydrocarbon advection, dispersion, surface spreading, entrainment, dissolution, biodegradation, emulsification, volatilisation and shoreline interaction. The weathering model (Daling *et al.,* 1997) is supported by an extensive oil library that contains detailed, laboratory-derived data for a wide range of hydrocarbons subjected to typical environmental conditions. OSCAR enables simulation of a hydrocarbon release scenario in deterministic mode (i.e. a scenario is simulated with one start date with spatial results available at fixed time intervals over the duration of the simulation) or stochastic mode (i.e. a scenario is simulated a number of times with varying start dates, and the results are outputted spatially in a probabilistic manner).

3.2 Selection of Hydrocarbon Modelling Analogues

Oil spill modelling in OSCAR is undertaken by selecting a hydrocarbon analogue from within the SINTEF Oil Library that provides the best match to the expected (target) hydrocarbon. The process for selecting the modelling analogue for Caley is described next.

3.2.1 Modelling Analogue for Caley

SINTEF's LAVRANS condensate was selected as the modelling analogue for Caley. A comparison of the bulk properties (Table 8) indicates the following:

– The specific gravity/API gravity of the modelling analogue LAVRANS is close to that of Caley. LAVRANS is a slightly heavier condensate (i.e. more conservative).
– The wax content (6%) of LAVRANS is lower than that of Caley (9.2%), though both oils have higher wax contents than is typical for condensates.
– The pour point of LAVRANS (-6°C) is higher than that of Caley (<-15°C).
– The LAVRANS asphaltene content (0.01%) is <0.5% reported for Caley.
– The LAVRANS viscosity of 2 cSt (measured at 20°C) is slightly higher (i.e. LAVRANS is slightly 'thicker' and more conservative) than that of Caley (1.878 cSt).

Table 8 Comparison of whole oil properties of Caley and SINTEF LAVRANS

Parameter	Caley (Intertek, 2020)	SINTEF Analogue: LAVRANS
API	51.4	47.8
Specific Gravity	0.7737	0.789
Wax Content (%)	9.2	6
Pour Point (°C)	<-15	-6
Asphaltene (%)	<0.5	0.01
Viscosity (cSt)	1.878 (@20°C)	2 (@20°C)

A comparison of the distillation curves of LAVRANS and Caley is presented in Figure 11. The distillation curve is derived from laboratory tests to determine the percentage of hydrocarbon evaporated (recovered) when heated to various temperatures (or 'cuts'). Lighter oil components evaporate under lower temperatures, whereas heavier oil components have a greater tendency to remain in liquid state, requiring higher temperatures to evaporate. This is analogous to oil weathering in the marine environment, whereby lighter components have a higher tendency to evaporate, dissolve or decay, and heavier components tend to persist as liquid hydrocarbon for extended durations. The distillation curve therefore provides a reasonable prediction of the relative proportions of hydrocarbon components that will have rapid rates of weathering and the relative proportions that will persist. The comparison of the distillation curves of LAVRANS and the Caley match very well, suggesting the hydrocarbons have similar weathering behaviour.

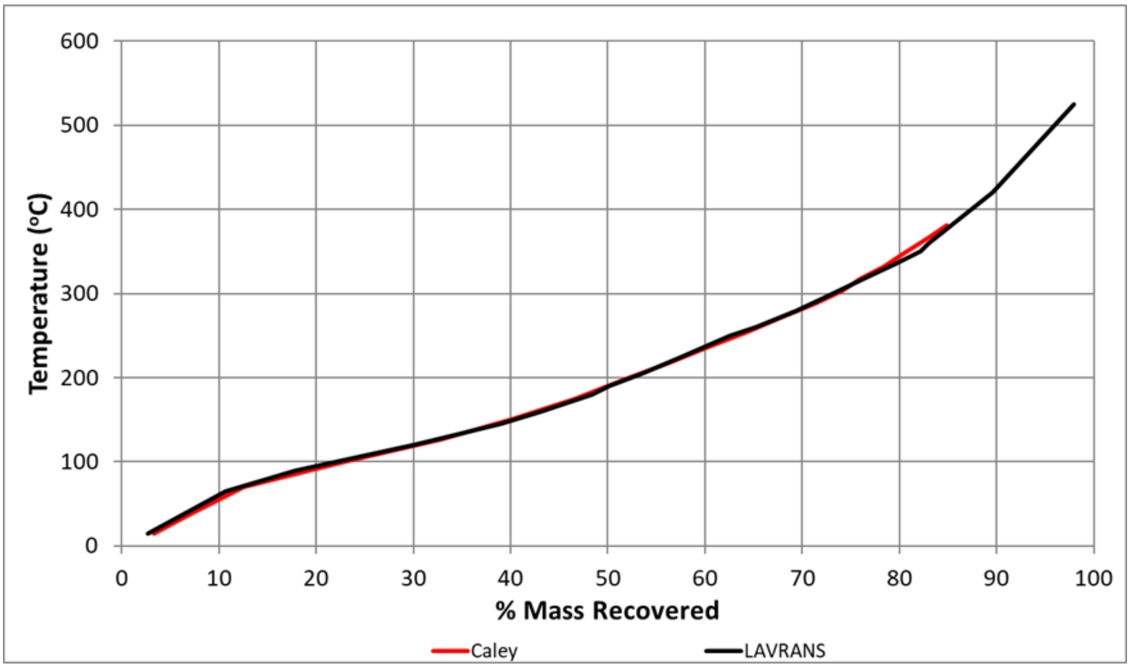

Figure 11 Comparison of distillation curves for Caley and LAVRANS

3.3 Hydrocarbon Weathering

A preliminary analysis of hydrocarbon weathering was undertaken with the SINTEF Oil Weathering Model (OWM). OWM predicts the mass balance partitioning of hydrocarbons (i.e. evaporation, surface, dispersed subsurface) and change in viscosity and pour point under steady-state met-ocean conditions. OWM simulations were run for sustained wind speeds of 1 m/s (low winds), 5 m/s (moderate winds) and 10 m/s (high winds). The simulations are based on a test case of 100 m^3 of hydrocarbon released instantaneously onto the sea surface.

3.3.1 LAVRANS

The results of the weathering analyses for the modelling analogue LAVRANS are presented in Figure 12.

Evaporation is the primary weathering mechanism for volatile condensates such as LAVRANS. Under low wind speeds of 1 m/s, approximately 65% of the surface slick is predicted to evaporate after 5 days (120 hours) while wind-driven dispersion into the water column does not occur under these relatively calm conditions. Under moderate wind speeds of 5 m/s, approximately 62% of the surface slick, which is slightly lower than the calm condition (1 m/s winds) due to wind-driven dispersion of a significant portion of the oil (35% by 48 hours and 38% after 72 hours) into the water column which reduces the amount of surface oil available for evaporation. High wind speeds of 10 m/s are predicted to rapidly (after only 12 hours) disperse (45%) and evaporate (55%) the oil with no surface slick remaining thereafter.

LAVRANS has a negligible tendency for emulsion formation (0% water content in the slick predicted under the wind conditions assessed).

The predicted changes in viscosity and pour point of the surface oil slick due to weathering are presented in Figure 13 and Figure 14, respectively. The viscosity of the surface slick was predicted to increase from ~3 cP after 0.5 hours to ~26 cP after 12 hours for the high wind (10 m/s) scenario (after which time the remaining surface slick is entirely entrained by wind activity) and up to ~36 cP after 5 days (120 hours) for the low wind (1 m/s) scenario, with additional weathering and viscosity increase anticipated to occur beyond this time. Similarly, the pour point increases as the oil weathers from ~-2-8°C after 0.5 hours, reaching 29°C after 12 hours for high winds (10 m/s) and 33°C after 5 days (120 hours) for low winds (1 m/s). These viscosity and pour point changes within the first 5 days are not likely to impact the efficacy of response measures (e.g. dispersant application) on reducing surface oil.

It is noted that the pour point of LAVRANS is predicted to reach 29-33°C (depending on wind conditions) after weathering. This exceeds typical surface water temperatures (26-29°C, section 2.3.3), which would suggest that the oil would begin to gel or solidify after weathering, however this is not reflected in the viscosity which remains relatively low. Additional information on the weathering dynamics of LAVRANS was provided by SINTEF as follows:

– In the case of this waxy condensate, the ‘gelling’ process, were it to occur, would involve the wax forming a physical network structure within the oil, which hardens it. However, this process is interrupted by wave motion continually breaking up the waxy structure. So, while it might begin to gel if left undisturbed, this doesn’t occur under the oceanic conditions simulated, nor did it occur under laboratory tests that are designed to be representative of oceanic conditions. This explains how the pour point can increase but the viscosity can remain quite low in an oceanic setting.
– The LAVRANS residue was not measured to have a high viscosity during the laboratory testing of this oil, so in this regard the weathering results agree with the laboratory testing. It was noted that the actual process of measuring viscosity can introduce shear forces into the oil which cause the wax network to break down (similar to how the waves break it down as described above).
– In conclusion, the oil would likely have the potential to form a ‘gel’ or solidified residue if left undisturbed, however this behaviour was not noted in the laboratory studies, and further is not likely to occur under oceanic conditions.

3.4 Stochastic Hydrocarbon Fate and Transport Assessment

3.4.1 Stochastic Configurations

Far-field spill modelling was carried out with OSCAR. The model was configured in stochastic mode to simulate a range of environmental conditions. The start dates for the LOWC stochastic simulations were staggered approximately fortnightly across five years of hydrodynamic and wind data. A total of 150 individual 'realisations' made up the full stochastic simulation set for each of the LOWC spill scenarios. For each set of stochastic realisations, OSCAR spatially tracked the surface oil, total submerged oil in the water column, dissolved oil and oil on shorelines. The 'total submerged oil' is comprised of dissolved oil and entrained oil (or droplets), and therefore provides a conservative (over) representation of the NOPSEMA (2019) thresholds for entrained oil.

To present this large amount of simulated data in a meaningful way, contact thresholds are applied to each of the hydrocarbon components and OSCAR generates statistical spatial outputs of the instances when and where each threshold was exceeded. For example, if a contact threshold of 100 ppb is applied to the dissolved component, the stochastic output from OSCAR will present the area of effect (potentially impacted) and associated probabilities (amongst other statistics) for which the concentration of dissolved hydrocarbons exceeded 100 ppb at any model grid cell during any of the realisations. The stochastic configurations for each spill scenario are summarised in Table 9.

3.4.2 Processing of Stochastic Results

The stochastic outputs for surface, total submerged oil, dissolved and shoreline hydrocarbons were processed in the manner described next.

Probability of Instantaneous Exposure

The *'probability of instantaneous exposure'* indicates the percentage of realisations that a threshold was exceeded at any instant at a particular location. The thresholds may be an instantaneous concentration (ppb), a time-integrated concentration (ppb.hr) or a mass per unit area (g/m^2).[4]

Arrival Time

The *'arrival time'* indicates the amount of time from the start of a realisation (i.e. the start of the release) until an adopted threshold is first exceeded. For stochastic simulations, the *'minimum arrival time'* is the shortest arrival time from any single realisation. This statistic is evaluated for individual cells in the model grid. When reported for receptor regions consisting of multiple cells, the minimum value anywhere within the receptor region is reported.

Concentration

The *'concentration'* indicates the mass of oil per unit volume (i.e. submerged in seawater) or per unit area (i.e. on seawater surface or on shoreline) of the receiving environment. For stochastic simulations, the *'maximum concentration'* is the highest concentration from any single point in time, in any single realisation, and if applicable at any water depth. This statistic is evaluated for individual cells in the model grid. When reported for receptor regions consisting of multiple cells, the maximum value anywhere within the receptor region boundary is reported.

Time-Averaged Outputs

'*Time-averaged'* data (e.g. time-averaged concentration) are reported for a number of parameters. For stochastic realisations, time averaging is calculated over the times at which a parameter exceeds the specified threshold. For example, when considering dissolved hydrocarbons concentration above a threshold of 100 ppb, the '*time-averaged concentration'* for a model cell will be the average concentration in that cell when the concentration was above 100 ppb (i.e. the average is not reduced by the periods in which no dissolved hydrocarbons were present, or dissolved hydrocarbons were below the threshold value).

---

[4] Toxicity thresholds should account for intensity, duration and frequency. The instantaneous approach (ppb) does not account for exposure duration.

Table 9 Summary of stochastic simulation configuration

Parameter	Apus Base Case Subsea LOWC	Apus Base Case Surface LOWC	Apus Alternate Subsea LOWC	Apus Alternate Surface LOWC	Source/Justification
Location	19° 11' 25.29" S 118° 59' 10.64" E				Apus-1 well location (advised by Santos, selected as the worst-case location as described in section 2.3.1.1)
Hydrocarbon Modelling Analogue	LAVRANS				*LAVRANS* selected as the modelling analogue for Caley (Section 3.2.1) in the SINTEF oil library
Release Depth	72 m	0 m (sea surface)	72 m	0 m (sea surface)	Advised by Santos
Diameter of subsea release orifice (m)	0.30	NA	0.21	NA	Advised by Santos. Surface spills do not use the diameter as an input as the hydrocarbon is initialised as floating oil on the sea surface.
Simulation Period	All months of the year				Advised by Santos
Liquid Release Volume	10,982,250 STB (1,745,986 m^3)	10,858,774 STB (1,746,355 m^3)	8,964,764 STB (1,425,241 m^3)	8,377,354 STB (1,331,852 m^3)	Advised by Santos
Gas Release Volume	19,255 MMscf (545.25 million sm^3)	NA	15,718 MMscf (445.01 million sm^3)	NA	Advised by Santos. Surface spills do not require a gas input as gas discharged is lost directly to the atmosphere.
Release Duration	77 days				Advised by Santos
Simulation Duration	112 days (16 weeks)				Sufficient duration following cessation of the release to allow environmental concentrations to reduce below the selected thresholds
Approximate interval between sequential stochastic realisation start dates	2 weeks				Sufficiently small interval to characterise stochastic range of oil spill effects
Threshold for Shoreline Hydrocarbons	10 g/m^2, 100 g/m^2 and 1,000 g/m^2				On the basis of NOPSEMA Bulletin #1 (NOPSEMA, 2019)
Thresholds for Surface Hydrocarbons	1 g/m^2, 10 g/m^2, and 50 g/m^2				On the basis of NOPSEMA Bulletin #1 (NOPSEMA, 2019)
Threshold for Total Submerged Oil	10 ppb and 100 ppb				On the basis of NOPSEMA Bulletin #1 (NOPSEMA, 2019)[5]
Threshold for Dissolved Hydrocarbons	10 ppb, 50 ppb and 400 ppb				On the basis of NOPSEMA Bulletin #1 (NOPSEMA, 2019)

[5] Note: the NOPSEMA thresholds refer to an entrained concentration only (not total submerged oil, which is entrained + dissolved oil). OSCAR outputs are provided as total submerged oil values. The entrained thresholds specified by NOPSEMA are applied directly as total submerged oil thresholds in this assessment, which is a conservative approach given that entrained oil contributes only partially to the calculation of total submerged oil.

Accumulated Oil Ashore

Oil on shorelines is tracked by OSCAR as an accumulated value for the stochastic simulations. The calculation for accumulated oil is the sum of all oil that has arrived at a shoreline cell over the duration of the simulation. In this manner, it does not consider weathering losses due to evaporation or washing of the shoreline by waves. The accumulated value will therefore be a conservative over-estimate of the peak oil mass at a shoreline when compared to the deterministic prediction, which does consider these loss mechanisms. In contrast, the accumulated oil ashore for deterministic simulations in OSCAR accounts for weathering losses on the shoreline due to evaporation and degradation, as well as washing of the shoreline by waves.

Scaling Analysis of Shoreline Loading of Small Islands

Three small Australian islands (Cartier Island, Ashmore Reef and Bedout Island) have smaller characteristic length scales (l_{Island}) than the minimum model shoreline length (~5.7 km [l_{Grid}] which is the diagonal length of the ~4 km model cells). A scaling analysis to reduce the simulated shoreline loading onto the larger modelled islands (L_{Grid}) was used to estimate a more realistic loading onto the actual small island dimensions (L_{Island}) on the basis of the model output where:

$$L_{Island} = \frac{l_{Island}}{l_{Grid}} L_{Grid}$$

The shoreline scaling factors (l_{island}/l_{grid}) used for the small islands are presented in Table 10.

Table 10 Small island scaling factors

Receptor Name	l_{Island} (km)	l_{Grid} (km)	Scaling Factor (l_{island}/l_{grid})
Cartier Island	0.6	5.7	11%
Ashmore Reef	5.0	39.8	13%
Bedout Island	1.1	5.7	19%

3.5 Deterministic Assessment

The stochastic simulation output provides a probabilistic temporal and spatial representation of potential impacts from an oil spill incident. To further inform the OPEP, individual stochastic realisations were selected to run in OSCAR's deterministic mode to characterise shoreline loading (i.e. loads) and the mass balance of the released oil in the marine environment (e.g. proportion of released oil lost to decay or volatilisation, proportion remaining as droplets).

The deterministic simulations were run only for the base case scenarios (worst-case flow rates) and were selected based on the following criteria:

– Highest accumulated shoreline loading >10 g/m^2 and >100 g/m^2 for the surface and subsea LOWC scenarios
– Highest surface oil mass >50 g/m^2 for whichever is higher of the surface/subsea LOWC scenarios
– Minimum arrival time of accumulated shoreline loading >10 g/m^2 and >100 g/m^2 for whichever is shorter of the surface/subsea LOWC
– Maximum length of accumulated shoreline loading >10 g/m^2 and >100 g/m^2 for whichever is longer of the surface/subsea LOWC.

Further, the deterministic simulations of the highest accumulated shoreline loading were run with and without the inclusion of a dispersant application plan. The following dispersant response strategies were evaluated via deterministic simulations of the selected realisations of the surface and subsurface LOWC scenarios:

– For the selected surface LOWC realisation, deterministic simulations only evaluated surface dispersant application (SDA) via vessels and aircraft, with dispersant only being applied outside of an exclusion zone of 25 km radius around the Apus-1 well location.

– For the above scenario, an additional SDA response was simulated which allowed dispersant application in the immediate vicinity of the well site, rather than outside of a 25 km radius exclusion zone. The purpose was to evaluate the benefit of the exclusion zone in allowing evaporation of oil from the surface slick prior to chemically dispersing the oil into the water column. This simulation was compared to the simulation with the dispersant application exclusion zone to estimate differences between the two strategies.
– For the selected subsea LOWC realisation, deterministic simulations were carried out of subsea dispersant injection (SSDI) and a combined SSDI and SDA (i.e. the two responses occurring concurrently) to evaluate the relative benefit of each approach.

The configurations of the SDA and SSDI response plans are described next.

3.5.1 Surface Dispersant Application Plan

Surface Dispersant Application (SDA) was simulated with the OSCAR response module that included the use of vessels, Fixed Wing Aerial Dispersant Capability (FWADC) aircraft and Hercules aircraft as summarised in Table 11. Further, varying mobilisation and operation times for each individual vessel and aircraft were included in the response strategy as summarised in Figure 15, including up to 8 vessels, up to 8 FWADC and 1 Hercules.

Table 11: Summary of surface dispersant application mitigation strategy[6]

Strategy Element	Vessel/s	Aircraft (FWADC)	Aircraft (Hercules)
Base of operations (location)	Port Hedland	Port Hedland	Port Hedland
Downtime at base (refuelling etc.)	0.5 hrs	1.5 hrs	2.7 hrs
Daily operation hours	12 (daylight only)	12 (daylight only)	12 (daylight only)
Cruise speed	13 knots	160 knots	300 knots
Operational speed (when applying dispersants)	5 knots	90 knots	150 knots
Dispersant tank size	10 m^3	3 m^3	13 m^3
Dispersant application rate	1:25		
Dispersant efficacy	40%		
Oil searching strategy	Thickest Oil		
Minimum thickness threshold	>50 µm		
Maximum viscosity threshold	<10,000 cSt		
Exclusion zones	Australian Marine Parks (Multiple Use Zones allowed), State Marine Parks, State Waters Within 10 km of water depths <10 m Within exclusion zones of offshore facilities Not applied within 25 km of the well site[7]		

[6] Strategy inputs provided by Santos.
[7] The 25 km exclusion zone allows for natural evaporation from the surface slick prior to chemically dispersing the oil (and preventing further evaporation until resurfacing). 25 km allows for ~24 hours of evaporation to occur, assuming a typical current speed of 0.25 m/s (section 2.3.1), which will yield evaporation of ~60% of the oil under moderate winds of 5 m/s (section 3.3.1).

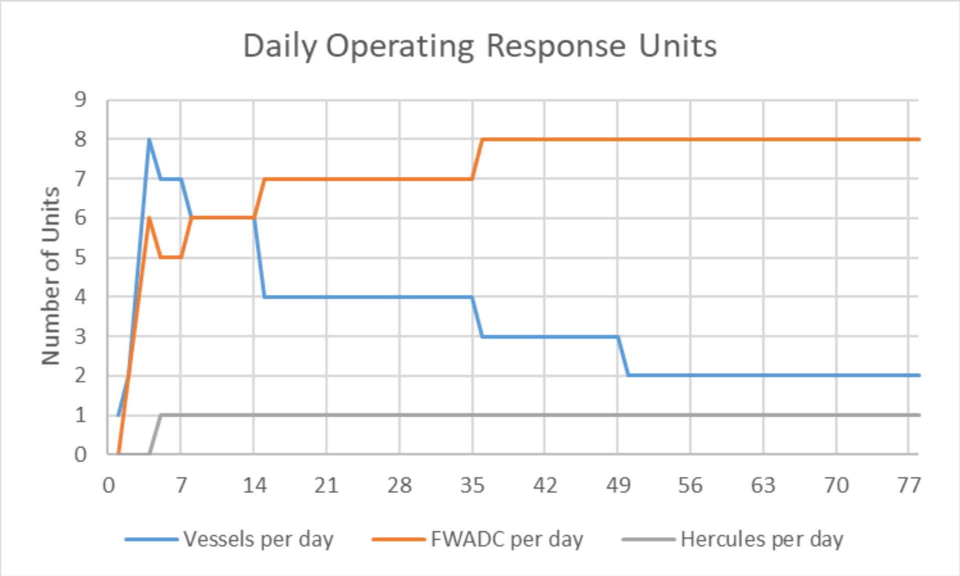

Figure 15 *Summary of response asset availability for the SDA plan*

3.5.2 Subsea Dispersant Injection Plan

Subsea Dispersant Injection (SSDI) involves injecting dispersant into the subsea plume at the release orifice. The response plan provided by Santos specified SSDI beginning 9 days after the start of the release, with an application rate of 1:100 (1 part dispersant to 100 parts liquid condensate) and a dispersant efficacy of 75%. For the subsea LOWC scenario, this application rate results in the use of 15,587 m^3 of dispersant applied to the subsea plume after day 9.

SSDI is configured in OSCAR by specifying the start and end days of SSDI injection and the dispersant efficacy (i.e. mixing efficiency). For the portion of the volume treated by SSDI, the simulated droplets in the subsea plume are assigned a reduced oil-water interfacial tension (reduced to half that of untreated oil). This has the effect of causing the liquid droplets (of the treated oil component) to break up into smaller droplets during release.

4. Results

4.1 Stochastic Modelling

Stochastic modelling outputs were evaluated for the following thresholds (also refer to Table 9 of section 3.4.1):

– Accumulated shoreline oiling above 10 g/m^2, 100 g/m^2 and 1,000 g/m^2.
– Instantaneous surface hydrocarbons above 1 g/m^2, 10 g/m^2 and 50 g/m^2.
– Instantaneous total submerged oil above 10 ppb and 100 ppb.
– Instantaneous dissolved hydrocarbons above 10 ppb, 50 ppb and 400 ppb.

The spatial extent of each threshold is described in the following sections with greater emphasis on the moderate thresholds (those underlined in bullet list above), which represent the lower limits for environmental impacts.

Further, the simulated shoreline oiling lengths of Cartier Island AMP, Ashmore Reef AMP and Bedout Island are an artefact of the relatively large model grid size of ~5.7 km compared to the smaller lengths of exposed shoreline at these locations (as described in section 3.4.2). Similarly, the maximum shoreline accumulations on the emergent shorelines would be less, as the total accumulation occurs on the larger modelled island length. Scaled shoreline accumulation and maximum oiled shoreline lengths are shown in parentheses for these receptors within the summary tables. Only the scaled values are referred to in the descriptions of the predicted shoreline oiling impacts, while the unscaled results can be seen in the summary tables.

4.1.1 Apus Base Case Subsea LOWC Scenario

4.1.1.1 Subsea Dynamics

The subsea dynamics of the Apus Base Case Subsea LOWC are highly energetic due to the gas volume that accompanies the release of liquid for this scenario. Whereas a surface release scenario will result in the gas being immediately lost to the atmosphere, the gas in a subsea discharge scenario contributes to the velocity and momentum of the subsea plume as it exits the release orifice.

At standard temperature and pressure (STP, which is 15°C and atmospheric pressure), the gas flow rate varies between 84.8 sm^3/s during the first week, decreasing to 80.5 sm^3/s by week 11 (Table 12). However, at the release depth of 72 m for the subsea scenario, the hydrostatic pressure compresses the gas, reducing the volumetric flow rate to 12.3-13.0 m^3/s.

Simulated momentum and buoyancy-scaled exit velocities range between 27.2-28.5 m/s that yield small median droplet sizes of 407-432 µm.

Table 12 Summary of near-field subsea plume dynamics

Week	Gas Flow Rate at STP[8] (sm^3/s)	Gas Flow Rate at Release Depth (m^3/s)	Liquid Oil Flow Rate (m^3/s)	Momentum and Buoyancy Scaled Effective Outlet Velocity (m/s)	Median Droplet Size (µm)

4.1.1.2 Accumulated Shoreline Oil

Shoreline oiling is assessed at three thresholds that represent low (10 g/m^2, visual/aesthetic threshold), moderate (100 g/m^2, impact threshold that may require clean-up effort), and high (1,000 g/m^2, requires intensive clean-up effort) accumulated shoreline loadings. A summary of the shoreline loading predictions is presented in Table 13, and loading probabilities and maximum accumulated shoreline loadings are mapped spatially in Figure 17 and Figure 18, respectively, for the three thresholds.

Shoreline loading above the low (10 g/m^2) threshold was predicted to occur up to ~1,300 km from the release site to the southwest (at Jurien Bay – Yanchep) and ~1,000 km to the north-northeast (at Indonesia – East) (Figure 17). At the moderate (100 g/m^2) and high (1,000 g/m^2) thresholds, the spatial extent of shoreline accumulation to the southwest was reduced to ~1,100 km and ~900 km, for each threshold respectively, while accumulation to the north-northeast remained at ~1,000 km distance (at Indonesia – East).

Shoreline accumulation above the moderate threshold (100 g/m^2) is summarised as follows:

– Across all shorelines, a 100% contact probability is predicted with a maximum accumulated shoreline load of 2,054 tonnes, a minimum arrival time of 3.5 days and a maximum length of oiled shoreline of 433 km.

– A very high contact probability of 81% was predicted for the proximal island receptor of Bedout Island. This receptor was predicted to receive a maximum shoreline accumulation of 63 tonnes, with a minimum arrival time of 3.5 days and maximum oiled shoreline length of 1 km (the island length).

– Moderately high contact probabilities of 30-57% were predicted at Clerke Reef MP, Imperieuse Reef MP, Dampier Archipelago, Montebello Islands, Barrow Island, Thevenard Islands, Southern Islands Coast, Muiron Islands and Ningaloo Coast North. Maximum accumulated shoreline loads at these locations were 1,014 tonnes at Imperieuse Reef MP, 919 tonnes at Clerke Reef MP, 849 tonnes at Dampier Archipelago and 102-420 tonnes at the other receptors. Minimum arrival times of shoreline loading at these locations ranged between 13.5 days to 30.5 days. Maximum predicted lengths of shoreline accumulation were between 11 km to 85 km, with the exception of Ningaloo Coast North (188 km).

– Moderate contact probabilities of 12-29% were predicted at Scott Reef South, Port Hedland-Eighty Mile Beach, Karratha-Port Hedland, Lowendal Islands, Ningaloo Coast South, Eighty Mile

[8] Standard Temperature and Pressure – The volume of gas is calculated assuming a temperature of 15°C and a pressure of 1 atm

Beach, and Roebuck – Eighty Mile Beach. Maximum accumulated shoreline loads at these receptors were between 52 tonnes and 642 tonnes. Minimum arrival times of shoreline loading at these locations ranged between 5.1 days and 53.9 days, while maximum predicted lengths of shoreline accumulation were between 6 km and 85 km.

– Low probabilities of contact (<10%) were predicted at Cartier Island AMP, Ashmore Reef AMP, Scott Reef North, King Sound, Broome North Coast, Middle Islands Coast, Shark Bay – Coast Outer, Abrolhos Islands Wallabi Group, Abrolhos Islands Pelsaert Group, Indonesia – East, Broome – Roebuck and Jurien Bay - Yanchep. Contact probabilities, accumulated shoreline loads, minimum arrival times and maximum oiled shoreline lengths for these receptors are summarised in Table 13.

A histogram of total shoreline loading above the moderate threshold (100 g/m^2) across the 150 stochastic realisations is presented in Figure 16 and a spatial summary of maximum accumulated shoreline oil is shown on Figure 18. Shoreline accumulation at the moderate threshold was predicted to occur for 100% of the realisations. No clear seasonal trend is evident in the shoreline loading predictions. Approximately half of the realisations resulted in shoreline accumulation greater than 500 tonnes (up to a maximum of 2,054 tonnes).

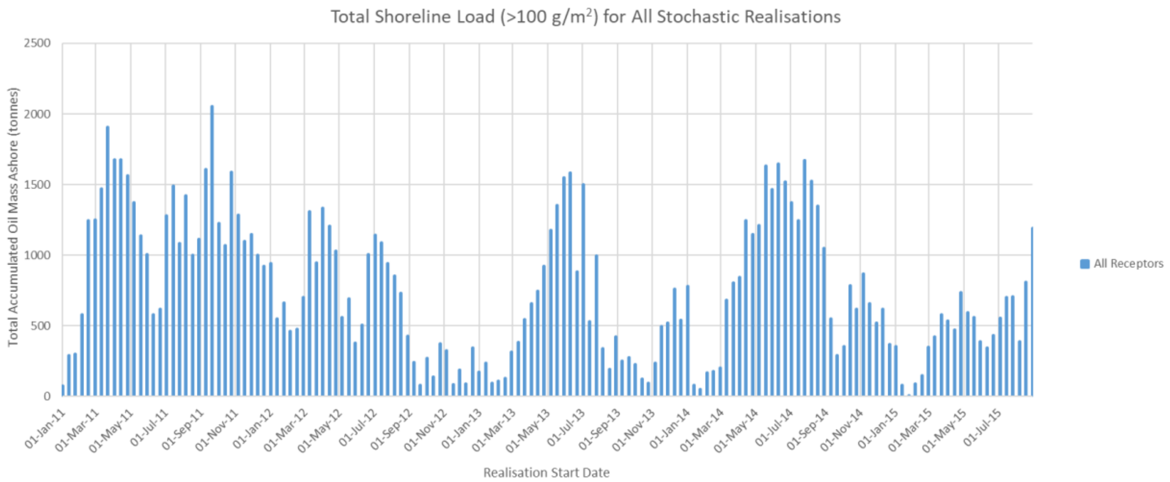

Figure 16 *Apus Base Case Subsea LOWC Scenario – Summary of total accumulated shoreline load for all stochastic realisations for the 100 g/m^2 threshold*

4.1.1.3 Surface Oil

Surface oiling is evaluated at three instantaneous contact thresholds representing low (1 g/m^2, visual/aesthetic threshold), moderate (10 g/m^2, lower limit for potential ecological impacts), and high (50 g/m^2, approximating concentrations that can be targeted during spill response) concentrations. A summary of the surface oil predictions are presented in Table 14, and contact probabilities and maximum surface oil concentrations are mapped spatially in Figure 19 and Figure 20 for the three thresholds, respectively.

Surface oil above the low threshold (1 g/m^2) was predicted to occur at distances up to ~1,100 km from the release location (Figure 19). Significant reductions in the spatial extent of surface oil are predicted for the moderate threshold (10 g/m^2) which extends up to ~550 km from the release location, while the high threshold (50 g/m^2) is further reduced in spatial extent to within ~225 km of the release location.

Surface oil impacts at the moderate threshold (10 g/m^2) include:

– A moderately high contact probability of 54% was predicted for the Eighty Mile Beach AMP, with a maximum time-averaged surface oil concentration of 43 g/m^2 and a minimum arrival time of 1.8 days.

– A moderate contact probability of 23% was predicted at Bedout Island, with a maximum time-averaged surface oil concentration of 42 g/m^2 and a minimum arrival time of 3.3 days.

– Low contact probabilities (<6%) were predicted at Mermaid Reef AMP, Port Hedland-Eighty Mile Beach, Glomar Shoals, Eighty Mile Beach, Rowley Shoals surrounds and Ningaloo - Offshore, with maximum time-averaged concentrations of 12-17 g/m^2 and minimum arrival times of 13.7 to 45.8 days.

4.1.1.4 Total Submerged Oil

Total submerged oil (entrained plus dissolved oil) is evaluated at low (10 ppb, potential exceedance of water quality triggers) and moderate (100 ppb, potential impacts) instantaneous contact thresholds. Total submerged oil predictions are summarised in Table 15 and contact probabilities are mapped spatially in Figure 21 for the two thresholds.

Total submerged oil at the low threshold (10 ppb) was predicted to occur up to ~1,800 km from the release location. At the moderate threshold (100 ppb), predicted contact reduced in spatial to within ~1,100 km from the release location.

Total submerged oil impacts at the moderate threshold (100 ppb) include:

– Very high contact probabilities were predicted at Eighty Mile Beach AMP (99%) and Bedout Island (73%), with maximum time-averaged concentrations at these receptors of 1,936 ppb and 1,037 ppb, respectively, and with minimum arrival times of 2.1 and 3.8 days, respectively.

– Moderately high contact probabilities of 30-58% were predicted at Glomar Shoals, Dampier Archipelago, Eighty Mile Beach, Kimberley AMP, Dampier AMP, Montebello AMP, Rowley Shoals surrounds and Ningaloo - Offshore. Maximum time-averaged concentrations at these locations ranged between 315 ppb and 1,987 ppb, with minimum arrival times of 10.4 to 24.3 days.

– Moderate contact probabilities of 12-28% were predicted at Mermaid Reef AMP, Clerke Reef MP, Imperieuse Reef MP, Port Hedland-Eighty Mile Beach, Karratha-Port Hedland, Rankin Bank, Montebello Islands, Barrow-Montebello Surrounds, Roebuck - Eighty Mile Beach, Ningaloo – Outer Coast North and Ningaloo – Outer NW. Maximum time-averaged concentrations at these locations ranged between 231 ppb and 1,823 ppb, with minimum arrival times of 5.2 to 25.9 days.

– Very low contact probabilities (<8%) occurred at several other receptor locations with contact probabilities, maximum time-averaged oil concentrations and minimum arrival times summarised in Table 15.

4.1.1.5 Dissolved Hydrocarbons

Dissolved hydrocarbons were evaluated at the low (10 ppb, potential exceedance of water quality triggers), moderate (50 ppb, potential sub-lethal toxic effects) and high (400 ppb, potential toxic lethal effects) instantaneous contact thresholds. A summary of the dissolved hydrocarbon predictions is presented in Table 16 and contact probabilities are mapped spatially in Figure 22 for the three thresholds.

Dissolved hydrocarbons at the low threshold (10 ppb) were predicted to extend a maximum distance of ~350 km from the release location. At the moderate threshold (50 ppb), the spatial extent was reduced to within ~150 km, while exceedance of the high threshold (400 ppb) was limited to within ~100 km of the release site.

Eighty Mile Beach AMP was the only receptor predicted to be contacted at the moderate threshold (50 ppb) with a very low contact probability of 5%, a maximum time-averaged concentration of 94 ppb and minimum arrival time of 4.8 days.

Table 13 Apus Base Case Subsea LOWC Scenario – Summary of shoreline oiling

4.1.2 Apus Base Case Surface LOWC Scenario

4.1.2.1 Accumulated Shoreline Oil

Shoreline oiling is assessed at three thresholds that represent low (10 g/m^2, visual/aesthetic threshold), moderate (100 g/m^2, impact threshold that may require clean-up effort), and high (1,000 g/m^2, requires intensive clean-up effort) accumulated shoreline loadings. A summary of the shoreline loading predictions is presented in Table 17, and loading probabilities and maximum accumulated shoreline loadings are mapped spatially in Figure 24 and Figure 25 for the three thresholds, respectively.

Shoreline loading above the low (>10 g/m^2) and moderate (100 g/m^2) thresholds was predicted to occur up to ~1,300 km northwest (at Indonesia – East) and south-west (at Abrolhos Islands Pelsaert Group) from the release site. At the high (1,000 g/m^2) threshold, the spatial extent of shoreline accumulation was reduced to ~900 km north-east (at Ashmore Reef AMP and Cartier Island AMP) and ~1,050 km southwest (at Shark Bay – Coast Outer).

Shoreline accumulation above the moderate threshold (100 g/m^2) is summarised as follows:

- Across all shorelines, a 100% contact probability is predicted with a maximum accumulated shoreline load of 5,125 tonnes, a minimum arrival time of 2.0 days and a maximum length of oiled shoreline of 500 km.
- A very high contact probability of 77% was predicted for the proximal island receptor of Bedout Island. This receptor was predicted to receive a maximum shoreline accumulation of 58 tonnes, with a minimum arrival time of 2 days and maximum oiled shoreline length of 1 km (the island length).
- Moderately high contact probabilities of 33-59% were predicted at Clerke Reef MP, Imperieuse Reef MP, Dampier Archipelago, Montebello Islands, Barrow Island, Thevenard Islands, Southern Islands Coast, Muiron Islands, Ningaloo Coast North, Eighty Mile Beach and Roebuck – Eighty Mile Beach. Maximum accumulated shoreline loads at these locations were 2,301 tonnes at Eighty Mile Beach, 2,040 tonnes at Imperieuse Reef MP, 1,455 tonnes at Clerke Reef MP and 178-865 tonnes at the other receptors. Minimum arrival times of shoreline loading at these locations ranged between 11.4 days to 30.6 days. Maximum predicted lengths of shoreline accumulation were between 11 km to 97 km, with the exception of Ningaloo Coast North (227 km) and Eighty Mile Beach (136 km).
- Moderate contact probabilities of 10-27% were predicted at Scott Reef North, Scott Reef South, Broome North Coast, Port Hedland-Eighty Mile Beach, Karratha-Port Hedland, Northern Islands Coast, Lowendal Islands, Ningaloo Coast South and Broome - Roebuck. Maximum accumulated shoreline loads at these receptors were 2,035 tonnes at Port Hedland-Eighty Mile Beach, 972 tonnes at Karratha-Port Hedland, 625 tonnes at Scott Reef South and between 44 tonnes and 198 tonnes at the other locations. Minimum arrival times of shoreline loading at these locations ranged between 2.9 days and 52.3 days, while maximum predicted lengths of shoreline accumulation were between 6 km and 91 km.
- Low probabilities of contact (<10%) were predicted at Cartier Island AMP, Ashmore Reef AMP, King Sound, Exmouth Gulf Coast, Shark Bay – Coast Outer, Zuytdorp Cliffs – Kalbarri, Kalbarri – Geraldton, Abrolhos Islands Easter Group, Abrolhos Islands Pelsaert Group and Indonesia – East. Contact probabilities, accumulated shoreline loads, minimum arrival times and maximum oiled shoreline lengths for these receptors are summarised in Table 17.

A histogram of total shoreline loading above the moderate threshold (100 g/m^2) across the 150 stochastic realisations is presented in Figure 23. Shoreline accumulation at the moderate threshold was predicted to occur for 100% of the realisations. No clear seasonal trend is evident in the shoreline loading predictions. Approximately half of the realisations resulted in shoreline accumulation greater than 1,000 tonnes (up to a maximum of 5,125 tonnes).

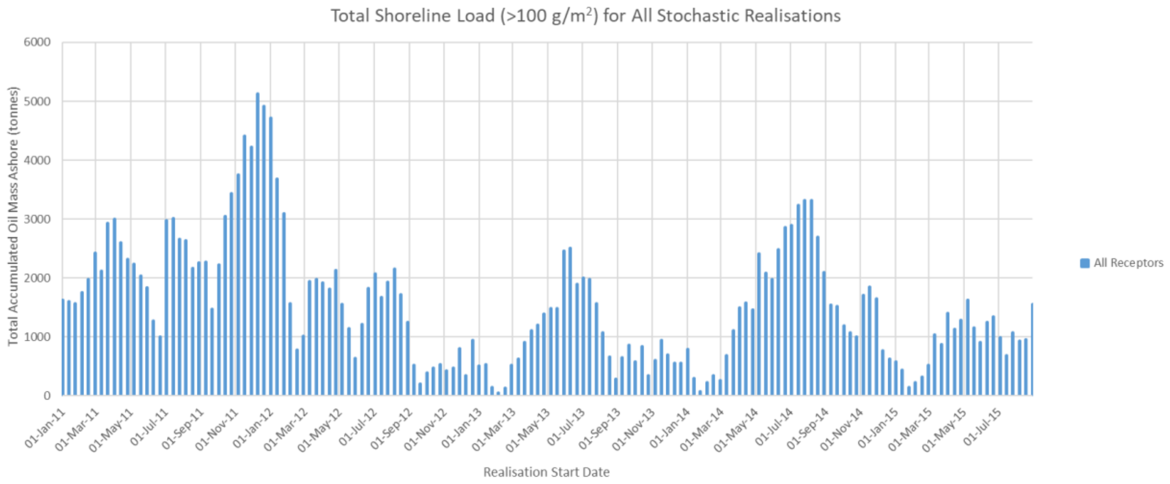

Figure 23 *Apus Base Case Surface LOWC Scenario – Summary of total accumulated shoreline load for all stochastic realisations for the 100 g/m^2 threshold*

4.1.2.2 Surface Oil

Surface oiling is evaluated at three instantaneous contact thresholds representing low (1 g/m^2, visual/aesthetic threshold), moderate (10 g/m^2, lower limit for potential ecological impacts), and high (50 g/m^2, approximating concentrations that can be targeted during spill response) concentrations. A summary of the surface oil predictions are presented in Table 18, with contact probabilities and maximum surface oil concentrations mapped spatially in Figure 26 and Figure 27 for the three thresholds, respectively.

Surface oil above the low threshold (1 g/m^2) was predicted to occur at distances up to ~1,100 km from the release location. The spatial extent of surface oil predicted for the moderate threshold (10 g/m^2) reduced to ~600 km, and the high threshold (50 g/m^2) spatial extent was restricted to within ~300 km of the release location.

Surface oil impacts at the moderate threshold (10 g/m^2) include:

– A high contact probability of 70% was predicted for the Eighty Mile Beach AMP, with a maximum time-averaged surface oil concentration of 150 g/m^2 and a minimum arrival time of 0.8 days.

– A moderately high contact probability of 47% was predicted at Bedout Island, with a maximum time-averaged surface oil concentration of 145 g/m^2 and a minimum arrival time of 1.5 days.

– Moderately low contact probabilities of 13-18% were predicted at Port Hedland-Eighty Mile Beach, Glomar Shoals, Eighty Mile Beach and Rowley Shoals surrounds, with maximum time-averaged surface oil concentrations of 15-30 g/m^2 and minimum arrival times of 2-16 days.

– Low contact probabilities (<6%) were predicted at Mermaid Reef AMP, Imperieuse Reef MP, Karratha-Port Hedland and Ningaloo - Offshore, with maximum time-averaged concentrations of 10-18 g/m^2 and minimum arrival times of 17.9 to 48.3 days.

4.1.2.3 Total Submerged Oil

Total submerged oil (entrained plus dissolved oil) is evaluated at low (10 ppb, potential exceedance of water quality triggers) and moderate (100 ppb, potential impacts) instantaneous contact thresholds. Total submerged oil predictions are summarised in Table 19 and contact probabilities are mapped spatially in Figure 28 for the two thresholds.

Total submerged oil at the low threshold (10 ppb) was predicted to occur up to ~1,800 km from the release location. At the moderate threshold (100 ppb), predicted contact was reduced in spatial extent to within 1,200 km from the release location.

Total submerged oil impacts at the moderate threshold (100 ppb) include:

– A very high contact probability of 94% was predicted at Eighty Mile Beach AMP, with a maximum time-averaged concentration of 2,611 ppb and minimum arrival time of 0.8 days.

- Moderate to high contact probabilities of 32-69% were predicted at Imperieuse Reef MP, Glomar Shoals, Dampier Archipelago, Rankin Bank, Eighty Mile Beach, Roebuck – Eighty Mile Beach, Kimberley AMP, Dmapier AMP, Montebello AMP, Rowley Shoals surrounds, Ningaloo – Offshore and Bedout Island. Maximum time-averaged concentrations at these locations ranged between 295 ppb and 1,866 ppb, with minimum arrival times of 1.9 to 21.3 days.
- Moderate contact probabilities of 11-29% were predicted at Mermaid Reef AMP, Clerke Reef MP, Port Hedland-Eighty Mile Beach, Karratha-Port Hedland, Montebello Islands, Barrow Island, Barrow-Montebello Surrounds, Ningaloo Coast North, Broome - Roebuck, Ningaloo – Outer Coast North and Ningaloo – Outer NW. Maximum time-averaged concentrations at these locations ranged between 190 ppb and 3,755 ppb, with minimum arrival times of 2 to 32.7 days.
- Low contact probabilities (<10%) occurred at several other receptor locations with contact probabilities, maximum time-averaged oil concentrations and minimum arrival times summarised in Table 19.

4.1.2.4 Dissolved Hydrocarbons

Dissolved hydrocarbons were evaluated at the low (10 ppb, potential exceedance of water quality triggers), moderate (50 ppb, potential sub-lethal toxic effects) and high (400 ppb, potential toxic lethal effects) instantaneous contact thresholds. A summary of the dissolved hydrocarbon predictions is presented in Table 20 and contact probabilities are mapped spatially in Figure 29 for the three thresholds.

Dissolved hydrocarbons at the low threshold (10 ppb) were predicted to extend a maximum distance of ~500 km from the release location. At the moderate threshold (50 ppb), the spatial extent was generally reduced in extent to within ~250 km, though a localised exceedance was predicted in one model cell at a distance of ~450 km from the release location. Exceedance of the high threshold (400 ppb) was limited to within ~150 km of the release site.

Dissolved hydrocarbon impacts at the moderate threshold (50 ppb) include:

- A moderately high contact probability of 60% was predicted at Eighty Mile Beach AMP, with a maximum time-averaged concentration of 346 ppb and a minimum arrival time of 0.8 days.
- A moderate contact probability of 28% was predicted at Bedout Island, with a maximum time-averaged concentration of 304 ppb and a minimum arrival time of 2 days.
- Very low contact probabilities (<5%) were predicted at Imperieuse Reef MP, Port Hedland-Eighty Mile Beach, Eighty Mile Beach and Rowley Shoals Surrounds. Maximum time-averaged concentrations at these receptors were 100-261 ppb with minimum arrival times of 3.7-28.4 days.

Table 17 Apus Base Case Surface LOWC Scenario – Summary of shoreline oiling

4.1.3 Apus Alternate Subsea LOWC Scenario

4.1.3.1 Subsea Dynamics

The subsea dynamics of the Apus Alternate Subsea LOWC are highly energetic due to the gas volume that accompanies the release of liquid for this scenario. Whereas a surface release scenario will result in the gas being immediately lost to the atmosphere, the gas in a subsea discharge scenario contributes to the velocity and momentum of the subsea plume as it exits the release orifice.

At standard temperature and pressure (STP, which is 15°C and atmospheric pressure), the gas flow rate varies between 68.8 sm^3/s during the first week, decreasing to 65.9 sm^3/s by week 11 (Table 21). However, at the release depth of 72 m for the subsea scenario, the hydrostatic pressure compresses the gas, reducing the volumetric flow rate to 10.7-10.2 m^3/s.

Simulated momentum and buoyancy-scaled exit velocities range between 46.1-44.1 m/s that yield very small median droplet sizes of 199-210 µm.

While the discharge rates of liquid condensate and gas are reduced compared to the Apus Base Case scenario, outlet velocities increase for the alternate well design due to the reduction in the orifice diameter (from 0.30 m base case to 0.21 m alternate). This yields a reduced droplet sizes relative to the base case subsea scenario, which results in longer durations of oil entrainment prior to surfacing.

Table 21 Summary of near-field subsea plume dynamics

Week	Gas Flow Rate at STP[10] (sm^3/s)	Gas Flow Rate at Release Depth (m^3/s)	Liquid Oil Flow Rate (m^3/s)	Momentum and Buoyancy Scaled Effective Outlet Velocity (m/s)	Median Droplet Size (µm)

4.1.3.2 Accumulated Shoreline Oil

Shoreline oiling is assessed at three thresholds that represent low (10 g/m^2, visual/aesthetic threshold), moderate (100 g/m^2, impact threshold that may require clean-up effort), and high (1,000 g/m^2, requires intensive clean-up effort) accumulated shoreline loadings. A summary of the shoreline loading predictions is presented in Table 22, and loading probabilities and maximum accumulated shoreline loadings are mapped spatially in Figure 31 and Figure 32, respectively, for the three thresholds.

Shoreline loading above the low (10 g/m^2) and moderate (100 g/m^2) thresholds was predicted to occur up to ~1,200 km from the release site to the southwest at Abrolhos Islands Pelsaert Group and ~1,000 km to the northeast at Indonesia East (Figure 31). At the high threshold (1,000 g/m^2) the spatial extent of shoreline accumulation was reduced to within ~950 km of the release site.

[10] Standard Temperature and Pressure – The volume of gas is calculated assuming a temperature of 15°C and a pressure of 1 atm

Shoreline accumulation above the moderate threshold (100 g/m^2) is summarised as follows:

– Across all shorelines, a 100% contact probability is predicted with a maximum accumulated shoreline load of 984 tonnes, a minimum arrival time of 5.8 days and a maximum length of oiled shoreline of 312 km.
– A very high contact probability of 77% was predicted for the proximal island receptor of Bedout Island. This receptor was predicted to receive a maximum shoreline accumulation of 64 tonnes, with a minimum arrival time of 5.8 days and maximum oiled shoreline length of 1 km (the island length).
– Moderately high contact probabilities of 30-54% were predicted at Clerke Reef MP, Imperieuse Reef MP, Dampier Archipelago, Montebello Islands, Barrow Island, Southern Islands Coast, Muiron Islands and Ningaloo Coast North. Maximum accumulated shoreline loads at these locations were 539 tonnes at Dampier Archipelago, 508 tonnes at Imperieuse Reef MP, 432 tonnes at Clerke Reef MP and 122-253 tonnes at the other receptors. Minimum arrival times of shoreline loading at these locations ranged between 14.7 days to 30.8 days. Maximum predicted lengths of shoreline accumulation were between 17 km to 85 km, except for Ningaloo Coast North (136 km).
– Moderate contact probabilities of 10-23% were predicted at Scott Reef South, Port Hedland-Eighty Mile Beach, Karratha-Port Hedland, Lowendal Islands, Thevenard Islands, Eighty Mile Beach, and Roebuck – Eighty Mile Beach. Maximum accumulated shoreline loads at these receptors were between 34 tonnes and 183 tonnes, apart from Scott Reef South (490 tonnes) and Port Hedland-Eighty Mile Beach (405 tonnes). Minimum arrival times of shoreline loading at these locations ranged between 12.6 days and 48.2 days, while maximum predicted lengths of shoreline accumulation were between 6 km and 57 km.
– Low probabilities of contact (<10%) were predicted at Kimberley Coast PMZ, Cartier Island AMP, Ashmore Reef AMP, Camden Sound, Scott Reef North, King Sound, Broome North Coast, Northern Islands Coast, Ningaloo Coast South, Shark Bay – Coast Outer, Abrolhos Islands Pelsaert Group, Indonesia – East and Broome – Roebuck. Contact probabilities, accumulated shoreline loads, minimum arrival times and maximum oiled shoreline lengths for these receptors are summarised in Table 22.

A histogram of total shoreline loading above the moderate threshold (100 g/m^2) across the 150 stochastic realisations is presented in Figure 30 and a spatial summary of maximum accumulated shoreline oil is shown on Figure 32. Shoreline accumulation at the moderate threshold was predicted to occur for 100% of the realisations. No clear seasonal trend is evident in the shoreline loading predictions. Approximately half of the realisations resulted in shoreline accumulation greater than 300 tonnes (up to a maximum of 984 tonnes).

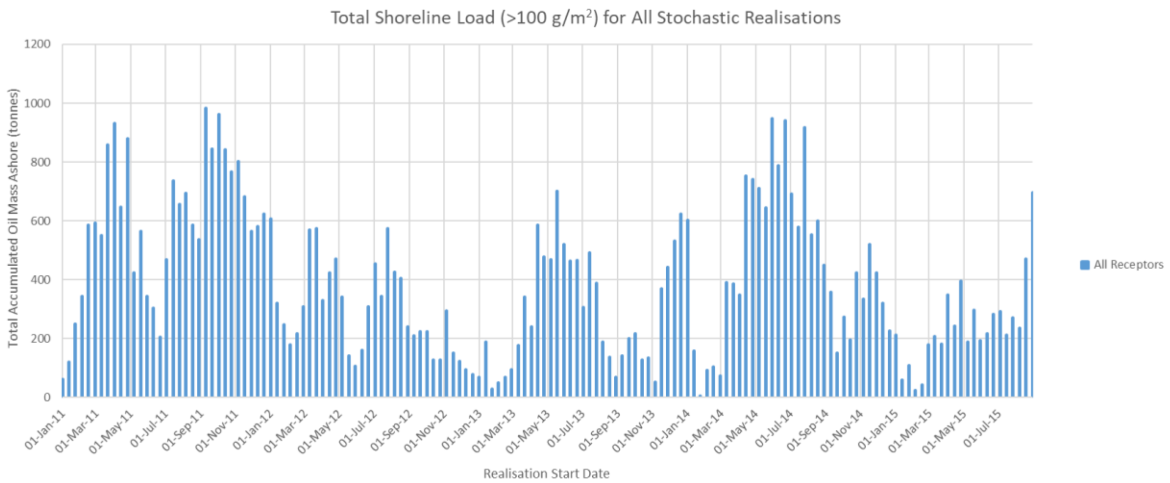

Figure 30 ***Apus Alternate Subsea LOWC Scenario – Summary of total accumulated shoreline load for all stochastic realisations for the 100 g/m^2 threshold***

4.1.3.3 Surface Oil

Surface oiling is evaluated at three instantaneous contact thresholds representing low (1 g/m^2, visual/aesthetic threshold), moderate (10 g/m^2, lower limit for potential ecological impacts), and high (50 g/m^2, approximating concentrations that can be targeted during spill response) concentrations. A summary of the surface oil predictions are presented in Table 23, and contact probabilities and maximum surface oil concentrations are mapped spatially in Figure 33 and Figure 34 for the three thresholds, respectively.

Surface oil above the low threshold (1 g/m^2) was predicted to occur at distances up to ~1,000 km from the release location (Figure 33). Significant reductions in the spatial extent of surface oil are predicted for the moderate threshold (10 g/m^2) which extends up to ~350 km from the release location, while the high threshold (50 g/m^2) is further reduced in spatial extent to primarily within ~100 km of the release location, though some isolated patches were predicted to occur up to ~200 km away.

Surface oil impacts at the moderate threshold (10 g/m^2) include:

– A moderately high contact probability of 43% was predicted for the Eighty Mile Beach AMP, with a maximum time-averaged surface oil concentration of 29 g/m^2 and a minimum arrival time of 3.2 days.
– A low contact probability of 7% was predicted at Bedout Island, with a maximum time-averaged surface oil concentration of 22 g/m^2 and a minimum arrival time of 13.1 days.

4.1.3.4 Total Submerged Oil

Total submerged oil (entrained plus dissolved oil) is evaluated at low (10 ppb, potential exceedance of water quality triggers) and moderate (100 ppb, potential impacts) instantaneous contact thresholds. Total submerged oil predictions are summarised in Table 24 and contact probabilities are mapped spatially in Figure 35 for the two thresholds.

Total submerged oil at the low threshold (10 ppb) was predicted to occur up to ~1,800 km from the release location. At the moderate threshold (100 ppb), predicted contact reduced in spatial to within ~1,100 km from the release location.

Total submerged oil impacts at the moderate threshold (100 ppb) include:

– Very high contact probabilities were predicted at Eighty Mile Beach AMP (98%) and Bedout Island (75%), with maximum time-averaged concentrations at these receptors of 1,673 ppb and 1,147 ppb, respectively, and with minimum arrival times of 1.8 and 3.7 days, respectively.
– Moderately high contact probabilities of 30-54% were predicted at Glomar Shoals, Eighty Mile Beach, Dampier AMP, Montebello AMP and Rowley Shoals surrounds. Maximum time-averaged concentrations at these locations ranged between 335 ppb and 1,545 ppb, with minimum arrival times of 11.2 to 13.6 days.
– Moderate contact probabilities of 11-25% were predicted at Imperieuse Reef MP, Port Hedland-Eighty Mile Beach, Karratha-Port Hedland, Dampier Archipelago, Rankin Bank, Roebuck - Eighty Mile Beach, Kimberley AMP, and Ningaloo – Offshore. Maximum time-averaged concentrations at these locations ranged between 195 ppb and 1,399 ppb, with minimum arrival times of 14.4 to 31.9 days.
– Very low contact probabilities (<9%) occurred at several other receptor locations with contact probabilities, maximum time-averaged oil concentrations and minimum arrival times summarised in Table 24.

4.1.3.5 Dissolved Hydrocarbons

Dissolved hydrocarbons were evaluated at the low (10 ppb, potential exceedance of water quality triggers), moderate (50 ppb, potential sub-lethal toxic effects) and high (400 ppb, potential toxic lethal effects) instantaneous contact thresholds. A summary of the dissolved hydrocarbon predictions is presented in Table 25 and contact probabilities are mapped spatially in Figure 36 for the three thresholds.

Dissolved hydrocarbons at the low threshold (10 ppb) were predicted to extend a maximum distance of ~250 km from the release location. At the moderate threshold (50 ppb), the spatial extent was reduced to within ~150 km, while exceedance of the high threshold (400 ppb) was limited to within ~100 km of the release site.

Eighty Mile Beach AMP was the only receptor predicted to be contacted at the moderate threshold (50 ppb) with a moderately low contact probability of 14%, a maximum time-averaged concentration of 133 ppb and minimum arrival time of 5.8 days.

Table 22 Apus Alternate Subsea LOWC Scenario – Summary of shoreline oiling

[11] Note: The curved lines of 'gaps' in the data are an artefact of the OSCAR software projecting the model outputs from the native model projection (Lat/Lon) onto a Universal Transverse Mercator (UTM) grid during the export process. No data is deleted during this process. The gaps do not have a material impact on the data reported in the results tables, only an aesthetic impact on these figures.

4.1.4 Apus Alternate Surface LOWC Scenario

4.1.4.1 Accumulated Shoreline Oil

Shoreline oiling is assessed at three thresholds that represent low (10 g/m^2, visual/aesthetic threshold), moderate (100 g/m^2, impact threshold that may require clean-up effort), and high (1,000 g/m^2, requires intensive clean-up effort) accumulated shoreline loadings. A summary of the shoreline loading predictions is presented in Table 26, and loading probabilities and maximum accumulated shoreline loadings are mapped spatially in Figure 38 and Figure 39 for the three thresholds, respectively.

Shoreline loading above the low (10 g/m^2) threshold was predicted to occur up to ~1,100 km northwest (at Indonesia – East) and ~1,400 km south-west (at Jurien Bay - Yanchep) from the release site. At the moderate (100 g/m^2) threshold, the spatial extent of shoreline accumulation was reduced to ~1,100 km north-east and 1,200 km south-west, while at the high (1,000 g/m^2) threshold, the maximum spatial extent of shoreline accumulation up to ~900 km from the release site.

Shoreline accumulation above the moderate threshold (100 g/m^2) is summarised as follows:

- Across all shorelines, a 100% contact probability is predicted with a maximum accumulated shoreline load of 3,573 tonnes, a minimum arrival time of 2.0 days and a maximum length of oiled shoreline of 404 km.
- A very high contact probability of 76% was predicted for the proximal island receptor of Bedout Island. This receptor was predicted to receive a maximum shoreline accumulation of 57 tonnes, with a minimum arrival time of 2 days and maximum oiled shoreline length of 1 km (the island length).
- Moderately high contact probabilities of 31-57% were predicted at Clerke Reef MP, Imperieuse Reef MP, Dampier Archipelago, Montebello Islands, Barrow Island, Thevenard Islands, Southern Islands Coast, Muiron Islands, Ningaloo Coast North and Roebuck – Eighty Mile Beach. Maximum accumulated shoreline loads at these locations were 1,474 tonnes at Imperieuse Reef MP, 1,186 tonnes at Clerke Reef MP and 98-548 tonnes at the other receptors. Minimum arrival times of shoreline loading at these locations ranged between 12.4 days to 31.2 days. Maximum predicted lengths of shoreline accumulation were between 11 km to 85 km, with the exception of Ningaloo Coast North (193 km).
- Moderate contact probabilities of 10-29% were predicted at Scott Reef South, Broome North Coast, Port Hedland-Eighty Mile Beach, Karratha-Port Hedland, Northern Islands Coast, Lowendal Islands, Ningaloo Coast South and Eighty Mile Beach. Maximum accumulated shoreline loads at these receptors were 1,558 tonnes at Port Hedland-Eighty Mile Beach, 1,465 tonnes at Eighty Mile Beach and between 32 tonnes and 392 tonnes at the other locations. Minimum arrival times of shoreline loading at these locations ranged between 2.9 days and 56.0 days, while maximum predicted lengths of shoreline accumulation were between 6 km and 102 km.
- Low probabilities of contact (<10%) were predicted at Cartier Island AMP, Ashmore Reef AMP, Scott Reef North, Middle Islands Coast, Shark Bay – Coast Outer, Zuytdorp Cliffs – Kalbarri, Abrolhos Islands Wallabi Group, Abrolhos Islands Pelsaert Group, Indonesia – East and Broome - Roebuck. Contact probabilities, accumulated shoreline loads, minimum arrival times and maximum oiled shoreline lengths for these receptors are summarised in Table 26.

A histogram of total shoreline loading above the moderate threshold (100 g/m^2) across the 150 stochastic realisations is presented in Figure 37. Shoreline accumulation at the moderate threshold was predicted to occur for 100% of the realisations. No clear seasonal trend is evident in the shoreline loading predictions. Approximately half of the realisations resulted in shoreline accumulation greater than 800 tonnes (up to a maximum of 5,125 tonnes).

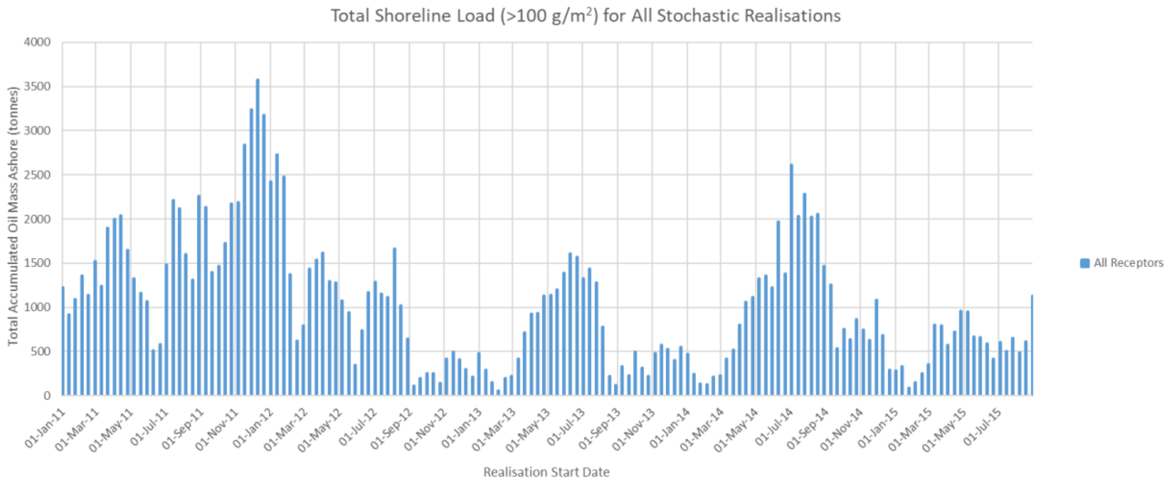

Figure 37 ***Apus Alternate Surface LOWC Scenario – Summary of total accumulated shoreline load for all stochastic realisations for the 100 g/m² threshold***

4.1.4.2 Surface Oil

Surface oiling is evaluated at three instantaneous contact thresholds representing low (1 g/m², visual/aesthetic threshold), moderate (10 g/m², lower limit for potential ecological impacts), and high (50 g/m², approximating concentrations that can be targeted during spill response) concentrations. A summary of the surface oil predictions are presented in Table 27, with contact probabilities and maximum surface oil concentrations mapped spatially in Figure 40 and Figure 41 for the three thresholds, respectively.

Surface oil above the low threshold (1 g/m²) was predicted to occur at distances up to ~1,000 km from the release location. The spatial extent of surface oil predicted for the moderate threshold (10 g/m²) reduced to ~525 km, and the high threshold (50 g/m²) spatial extent was restricted to within ~225 km of the release location.

Surface oil impacts at the moderate threshold (10 g/m²) include:

– A high contact probability of 66% was predicted for the Eighty Mile Beach AMP, with a maximum time-averaged surface oil concentration of 106 g/m² and a minimum arrival time of 1.2 days.

– A moderately high contact probability of 43% was predicted at Bedout Island, with a maximum time-averaged surface oil concentration of 104 g/m² and a minimum arrival time of 1.8 days.

– Moderately low contact probabilities of 11-13% were predicted at Port Hedland-Eighty Mile Beach, Glomar Shoals and Eighty Mile Beach, with maximum time-averaged surface oil concentrations of 19-26 g/m² and minimum arrival times of 2-12 days.

– Low contact probabilities (<5%) were predicted at Rowley Shoals surrounds and Ningaloo - Offshore, with maximum time-averaged concentrations of 15 g/m² and minimum arrival times of 30 to 33.9 days.

4.1.4.3 Total Submerged Oil

Total submerged oil (entrained plus dissolved oil) is evaluated at low (10 ppb, potential exceedance of water quality triggers) and moderate (100 ppb, potential impacts) instantaneous contact thresholds. Total submerged oil predictions are summarised in Table 28 and contact probabilities are mapped spatially in Figure 42 for the two thresholds.

Total submerged oil at the low threshold (10 ppb) was predicted to occur up to ~1,800 km from the release location. At the moderate threshold (100 ppb), predicted contact was reduced in spatial extent to within 1,200 km from the release location.

Total submerged oil impacts at the moderate threshold (100 ppb) include:

– A very high contact probability of 92% was predicted at Eighty Mile Beach AMP, with a maximum time-averaged concentration of 1,356 ppb and minimum arrival time of 0.9 days.

- Moderate to high contact probabilities of 30-63% were predicted at Imperieuse Reef MP, Glomar Shoals, Eighty Mile Beach, Roebuck – Eighty Mile Beach, Kimberley AMP, Dampier AMP, Montebello AMP, Rowley Shoals surrounds, Ningaloo – Offshore and Bedout Island. Maximum time-averaged concentrations at these locations ranged between 542 ppb and 1,888 ppb, with minimum arrival times of 2.0 to 23.1 days.
- Moderate contact probabilities of 11-29% were predicted at Mermaid Reef AMP, Clerke Reef MP, Port Hedland-Eighty Mile Beach, Karratha-Port Hedland, Dampier Archipelago, Rankin Bank, Montebello Islands, Barrow Island, Barrow-Montebello Surrounds, Broome - Roebuck, Ningaloo – Outer Coast North and Ningaloo – Outer NW. Maximum time-averaged concentrations at these locations ranged between 164 ppb and 1,581 ppb, with minimum arrival times of 2.0 to 31.3 days.
- Low contact probabilities (<10%) occurred at several other receptor locations with contact probabilities, maximum time-averaged oil concentrations and minimum arrival times summarised in Table 28.

4.1.4.4 Dissolved Hydrocarbons

Dissolved hydrocarbons were evaluated at the low (10 ppb, potential exceedance of water quality triggers), moderate (50 ppb, potential sub-lethal toxic effects) and high (400 ppb, potential toxic lethal effects) instantaneous contact thresholds. A summary of the dissolved hydrocarbon predictions is presented in Table 29 and contact probabilities are mapped spatially in Figure 43 for the three thresholds.

Dissolved hydrocarbons at the low threshold (10 ppb) were predicted to extend a maximum distance of ~450 km from the release location. At the moderate threshold (50 ppb), the spatial extent was reduced to within ~250 km, while exceedances of the high threshold (400 ppb) were limited to within ~100 km of the release site.

Dissolved hydrocarbon impacts at the moderate threshold (50 ppb) include:

- A moderately high contact probability of 56% was predicted at Eighty Mile Beach AMP, with a maximum time-averaged concentration of 312 ppb and a minimum arrival time of 0.9 days.
- A moderate contact probability of 25% was predicted at Bedout Island, with a maximum time-averaged concentration of 169 ppb and a minimum arrival time of 2.2 days.
- A very low contact probability of 3% was predicted at Port Hedland – Eighty Mile Beach, with a maximum concentration of 87 ppb and minimum arrival time of 4.6 days.

4.2 Deterministic Modelling

4.2.1 Selection of Realisations for Deterministic Simulations

As described in section 3.5, several realisations from the base case LOWC scenarios were selected to be run in OSCAR's deterministic mode to further inform development of the OPEP. The deterministic simulations were selected based on the following criteria:

- Highest accumulated shoreline loading >10 g/m^2 and >100 g/m^2 for the surface and subsea LOWC scenarios
- Minimum arrival time of accumulated shoreline loading >10 g/m^2 and >100 g/m^2 for whichever is shorter of the surface/subsea LOWC
- Maximum length of accumulated shoreline loading >10 g/m^2 and >100 g/m^2 for whichever is longer of the surface/subsea LOWC
- Highest surface oil mass >50 g/m^2 for whichever is higher of the surface/subsea LOWC scenarios.

A summary of the selected deterministic realisations is presented in Table 30 including the realisation numbers, start dates and a summary of predicted stochastic impacts relevant to the above selection criteria. Two LOWC realisations were also simulated with dispersant application response strategies (as detailed in section 3.5 and summarised in Table 30) to predict the potential reduction (benefit) in shoreline loading.

Table 30 Selected stochastic realisations for deterministic simulations

LOWC Scenario	Sim Number	Start of Release	Description of Impact	Mitigation Options Simulated
Apus Base Case Subsea	24	20-Sep-11	The highest accumulated shoreline mass above the low threshold (10 g/m^2) of 2,054 tonnes across all shorelines, including the following key outcomes: – 738 tonnes at Imperieuse Reef MP – 430 tonnes at Eighty Mile Beach – 390 tonnes at Clerke Reef MP – 319 tonnes at Roe - Eighty Mile Beach – 108 tonnes at Broome North Coast This is also the highest accumulated shoreline mass above the moderate threshold (100 g/m^2), with the same accumulated loads as listed above.	– Unmitigated – SSDI mitigated – SSDI+SDA mitigated
Apus Base Case Surface	31	9-Dec-11	The highest accumulated shoreline mass above the low threshold (10 g/m^2) of 5,127 tonnes across all shorelines, including the following key outcomes: – 2,303 tonnes at Eighty Mile Beach – 1,826 tonnes at Port Hedland-Eighty Mile Beach – 518 tonnes at Karratha-Port Hedland – 417 tonnes at Roebuck - Eighty Mile Beach This is also the highest accumulated shoreline mass above moderate threshold (100 g/m^2), with the same accumulated loads as listed above (for the 10 g/m^2 threshold) with the exception of a reduction of 2 tonnes at Eighty Mile Beach (i.e. accumulated load at Eighty Mile Beach above 100 g/m^2 was 2,301 tonnes)	– Unmitigated – SDA mitigated – SDA mitigated without the 25 km dispersant exclusion zone

LOWC Scenario	Sim Number	Start of Release	Description of Impact	Mitigation Options Simulated
Apus Base Case Surface	5	15-Feb-11	The earliest shoreline arrival time above the low threshold (10 g/m^2) including: – 2 days at Bedout Island – 2.9 days at Port Hedland-Eighty Mile Beach – Dampier Archipelago, Montebello Islands, Lowendal Islands, Barrow Islands, Thevenard Islands, Ningaloo Coast North and Shark Bay - Coast Outer after 62 days This is also the earliest shoreline arrival time above the moderate threshold (100 g/m^2), with generally similar arrival times as described above for the 10 g/m^2 threshold, with the exception of Lowendal Islands which was not contacted by accumualted oil above 100 g/m^2.	– Unmitigated
Apus Base Case Surface	9	2-Apr-11	The maximum length of shoreline oiled above the moderate threshold (10 g/m^2) of 523 km length across all shorelines, including the following key outcomes: – 210 km at Ningaloo Coast North – 80 km at Dampier Archipelago – 63 km at Ningaloo Coast South – 57 km at Barrow Island This is also the maximum length of accumulated shoreline mass above moderate threshold (100 g/m^2) of , including the following key outcomes: – 210 km at Ningaloo Coast North – 63 km at Dampier Archipelago – 57 km at Barrow Island – 51 km at Ningaloo Coast South	– Unmitigated
Apus Base Case Surface	101	15-Feb-14	The maximum surface oil mass above 50 g/m^2	– Unmitigated

4.2.2 Note on Deterministic Shoreline Predictions

As described in section 3.4.2, shoreline loading predictions for deterministic simulations account for weathering of oil on the shoreline (evaporation, decay and shoreline washing by wave action), whereas the accumulated shoreline load statistic reported for the stochastic simulations only considers total oil arrival and therefore ignores weathering processes that occur after each portion of oil is stranded ashore. The shoreline loading predictions presented in the following sections will therefore differ slightly to the stochastic results reported in Table 30. The deterministic peak oil loads are generally lower than the stochastic accumulated oil, while in some instances the minimum arrival times are also marginally increased and the oiled shoreline lengths are marginally reduced compared to the stochastic predictions. The differences in all cases are the result of the mitigative effect of the weathering processes on the oil stranded ashore, which delays and reduces impacts.

Another difference between the stochastic simulations and deterministic simulations is the inclusion of shoreline washing in the deterministic simulations, which is not incorporated in the stochastic predictions. Shoreline washing involves remobilisation of oil stranded ashore back into the water column by waves and tides. The shoreline washing mechanism can contribute to reductions in the deterministic oiled shoreline length when compared to the stochastic accumulated length in the same manner as the weathering (described above). However, it can also have the opposite effect and may in some cases yield increased oiled shoreline lengths for the deterministic simulations. This can occur because the remobilisation of portions of stranded oil introduces additional oil to the near-shore sea surface, which may then re-strike the shoreline in a different model cell that was otherwise uncontacted, thereby increasing the total oiled shoreline length. As such, while shoreline loading predictions are generally broadly similar between stochastic and deterministic simulations, some subtle variations may arise in some instances.

4.2.3 Apus Base Case Subsea LOWC Scenario #24

4.2.3.1 Unmitigated results

Stochastic realisation 24 of the Apus Base Case Subsea LOWC scenario resulted in the highest accumulated shoreline load (for that scenario) of 2,054 tonnes (of which the entire accumulated load exceeded 10 g/m^2 and 100 g/m^2).

The unmitigated simulation of this realisation resulted in a surface slick exceeding 10 µm thickness that extended up to ~180 km from the release location (Figure 45). Shoreline loading greater than 10 and 100 g/m^2 extended up to ~350 km of the release site (Figure 46). Total submerged oil exceeding 100 ppb extended up to ~700 km in sparse patches that travelled to the north-east of the release site, while the majority of exceedances were confined to within ~300 km of the release site (Figure 47). Dissolved hydrocarbons exceeding 50 ppb were limited in spatial extent to within ~50 km from the release location (Figure 47).

Shoreline accumulation for this realisation above both thresholds (10 g/m^2 and 100 g/m^2) began during day 32 at Roebuck – Eighty Mile Beach, with significant shoreline loading events continuing at a range of shoreline receptors until day 111. A time-series of shoreline accumulation impacts during this realisation is presented in Figure 48 (for 10 g/m^2) and Figure 49 (for 100 g/m^2), while summarised shoreline loading predictions are displayed in Table 32 and Table 33 for 10 and 100 g/m^2, respectively. The following key shoreline impacts are predicted at the moderate threshold (100 g/m^2):

– Imperieuse Reef MP received an instantaneous peak shoreline load of 616 tonnes, with shoreline accumulation beginning on day 81, and reaching the peak load on day 107, with a maximum oiled shoreline length of 57 km.
– Lower, but significant peak shoreline loads were also predicted at Clerke Reef MP (195 tonnes on day 110), Eighty Mile Beach (102 tonnes on day 61), Roebuck – Eighty Mile Beach (131 tonnes on day 51) and Bedout Island (17 tonnes on day 68).
– Across all shorelines combined, a peak oil loading of 853 tonnes occurred during day 103, with a maximum oiled shoreline length of 138 km.

The predicted hydrocarbon weathering (i.e. mass balance partitioning) for the specific met-ocean conditions encountered during the deterministic simulation is presented in Figure 50, and summarised as follows:

– Evaporation is the primary weathering mechanism with evaporated oil accounting for ~60% of the total oil mass by day 80.
– Oil decay (i.e. biodegradation) accounts for an additional ~30% of the oil by the end of the simulation (day 112).
– Several large wind-driven entrainment events occurred throughout the simulation resulting in increases in the mass of entrained droplets that were concomitant with decreases in the mass of surface oil. For this subsea discharge, entrained droplets typically accounted for ~15-30% of the total oil mass throughout the duration of the discharge (i.e. the first 77 days), while surface oil was proportionally lower (typically 1-10% of all oil) during this period.

4.2.3.2 Assessment of dispersant efficacy

The dispersant responses simulated for this scenario included SSDI and a combined SSDI and SDA response. A summary of the total dispersant applied by each response unit type (vessels and aircraft) for the SDA component of the combined SSDI and SDA response is presented in Table 31.

The effect of each response on the mass of surface oil and entrained droplets throughout the simulation is displayed in Figure 44, with spatial maps presented in Figure 45-Figure 47, comparisons of shoreline loading presented in Figure 48 (10 g/m^2) and Figure 49 (100 g/m^2), with summarised shoreline loading predictions displayed in Table 32 and Table 33 for 10 and 100 g/m^2, respectively .

4.2.3.2.1 SSDI response

Undertaking SSDI at an application ratio of 1:100 (dispersant:oil) from day 9 onwards results in the use of 15,587 m^3 of chemical dispersant.

This highly energetic subsea discharge with high exit velocities is predicted to generate small droplets, so the relative effect of further reductions in droplet diameters via SSDI to enhance dispersion is low. The median droplet size of oil treated by SSDI (75%) is predicted to be 270 µm in diameter relative to untreated median diameters of 413-432 µm (see Table 12 in the stochastic results for untreated droplet diameters). Negligible reductions to the surface slick mass were predicted from solely the SSDI response, with concomitant negligible increases in entrained oil mass (Figure 44).

In general, SSDI alone was not predicted to yield significant benefits to shoreline loading (Table 32-Table 34, Figure 48-Figure 49). At the moderate threshold (100 g/m^2) some increases in peak shoreline loads were predicted at various receptors, while a reduction was predicted at Imperieuse Reef MP. The increases in shoreline loading are likely from delayed surfacing of oil and less evaporative losses (which are the dominant weathering mechanism for this oil) and greater mass of surface oil in proximity to shoreline receptors at some locations. Overall, the accumulated shoreline load (i.e. the sum of oil arrival ignoring weathering) increased from 2,054 tonnes (unmitigated) to 2,439 tonnes (SSDI mitigated), though the altered timing of loading events for the SSDI scenario compared to the unmitigated scenario resulted in a slightly reduced instantaneous peak oil load of 811 tonnes on day 111 (SSDI mitigated) compared to 853 tonnes on day 103 (unmitigated).

4.2.3.2.2 Combined SSDI+SDA Response

For the SDA component of the combined SSDI+SDA response, the total daily dispersant application capacity for each response unit is 15 m^3 for FWADC (5 sorties per day, 3 m^3 dispersant tank), 40 m^3 for the Hercules (4 sorties, 10 m^3 dispersant tank) and 10 m^3 for vessels (1 sortie, 10 m^3 dispersant tank). Given the operational constraints (Section 3.5), the simulated dispersant application rates for the response aircraft (Hercules and FWADC) were ~80% of the daily capacity, with average daily application rates of 31.1 m^3 for the Hercules and 12.4 m^3 for the FWADC. The vessels applied on average 5.3 m^3 per day (53% of the daily capacity of 10 m^3 per day), with reduced efficiencies primarily being the result of long times required to cruise from Port Hedland to the response site that reduced the amount of daylight hours available for dispersant application. All response units were also limited by reduced availability of surface oil meeting the treatment threshold (>50 µm thickness) due to the initiation of SSDI from day 9. The total volume of dispersant applied throughout the combined SSDI+SDA response was 10,866 m^3 for the SDA component, and 15,587 m^3 for the SSDI component (total of 26,453 m^3).

In contrast to the solely SSDI response simulation, the combined SSDI+SDA response yields significant reductions in instantaneous surface oil loads of up to ~20,000 tonnes that were concomitant with approximately equal increases in the entrained oil mass (Figure 44). The SDA component of the response has therefore contributed significantly to reducing surface oil loads compared to the relatively ineffective SSDI response. The accumulated shoreline load reduces from 2,054 tonnes for the unmitigated simulation to 939 tonnes for the combined SSDI+SDA simulation (Table 34), indicating that 1,115 tonnes of oil were prevented from arriving at shorelines as a result of the response. At the moderate threshold (100 g/m^2), significant reductions in peak oil loads were also predicted at all contacted receptors, a total peak loading of 424 tonnes (reduced from 853 tonnes unmitigated) with Eighty Mile Beach and Roebuck – Eighty Mile Beach no longer receiving any oil loading above the threshold.

Table 31 Apus Base Case Subsea LOWC Scenario #24 – Summary of surface dispersant response (as part of combined SSDI+SDA response)

4.2.4 Apus Base Case Surface LOWC Scenario #31

4.2.4.1 Unmitigated results

Stochastic realisation 31 of the Apus Base Case Surface LOWC scenario resulted in the highest accumulated shoreline load (of all LOWC scenarios simulated) of 5,127 tonnes above 10 g/m^2 and 5,125 tonnes above 100 g/m^2.

The unmitigated simulation of this realisation resulted in a surface slick exceeding 10 µm thickness that extended up to ~300 km from the release location (Figure 52). Shoreline loading greater than 10 and 100 g/m^2 extended up to ~350 km of the release site (Figure 53). Total submerged oil exceeding 100 ppb extended up to ~400 km, while dissolved hydrocarbons exceeding 50 ppb were limited in spatial extent to within ~150 km from the release location (Figure 54).

Shoreline accumulation for this realisation above both thresholds (10 g/m^2 and 100 g/m^2) began during day 14 at Roebuck – Eighty Mile Beach, with significant shoreline loading events continuing at a range of shoreline receptors until day 80. A time-series of shoreline accumulation impacts during this realisation is presented in Figure 55 (for 10 g/m^2) and Figure 56 (for 100 g/m^2), while summarised shoreline loading predictions are displayed in Table 36 and Table 37 for 10 and 100 g/m^2, respectively. The following key shoreline impacts are predicted at the moderate threshold (100 g/m^2):

– Eighty Mile Beach received an instantaneous peak shoreline load of 1,504 tonnes, with shoreline accumulation beginning on day 28 and reaching the peak load on day 81, with a maximum oiled shoreline length of 119 km.
– Port Hedland-Eighty Mile Beach received an instantaneous peak shoreline load of 1,329 tonnes, with shoreline accumulation beginning on day 37 and reaching the peak load on day 54, with a maximum oiled shoreline length of 85 km.
– Lower, but significant peak shoreline loads were also predicted at Karratha-Port Hedland (657 tonnes on day 53), Roebuck – Eighty Mile Beach (606 tonnes on day 45) and Bedout Island (32 tonnes on day 34).
– Across all shorelines combined, a peak oil loading of 2,940 tonnes occurred during day 53, with a maximum oiled shoreline length of 302 km.

The predicted hydrocarbon weathering (i.e. mass balance partitioning) for the specific met-ocean conditions encountered during the deterministic simulation is presented in Figure 57, and summarised as follows:

– Evaporation is the primary weathering mechanism with evaporated oil accounting for ~80% of the total oil mass by day 100.
– Oil decay (i.e. biodegradation) accounts for the remaining ~20% of the oil by day 100.
– Several large wind-driven entrainment events occurred throughout the simulation resulting in increases in the mass of entrained droplets that were concomitant with decreases in the mass of surface oil. For this surface discharge, entrained droplets typically accounted for ~10-20% of the total oil mass throughout the duration of the discharge (i.e. the first 77 days), while surface oil was generally lower (typically 1-20% of all oil) during this period.

4.2.4.2 Assessment of dispersant efficacy

The dispersant responses simulated for this scenario included the standard SDA response, along with a modified SDA response that did not have the 25 km exclusion zone implemented (i.e. dispersant could be applied in close proximity to the well). A summary of the total dispersant applied by each response unit type (vessels and aircraft) for two SDA responses is presented in Table 35.

The effect of each response on the mass of surface oil and entrained droplets throughout the simulation is displayed in Figure 51, with spatial maps presented in Figure 52-Figure 54, comparisons of shoreline loading presented Figure 55 (10 g/m^2) and Figure 56 (100 g/m^2), with summarised shoreline loading predictions displayed in Table 36 and Table 37 for 10 and 100 g/m^2, respectively .

4.2.4.2.1 SDA Response

For the SDA response, the total daily dispersant application capacity for each response unit is 15 m^3 for FWADC (5 sorties per day, 3 m^3 dispersant tank), 40 m^3 for the Hercules (4 sorties, 10 m^3 dispersant tank) and 10 m^3 for vessels (1 sortie, 10 m^3 dispersant tank). Given the operational constraints (Section 3.5), the simulated dispersant application rates for the response aircraft (Hercules and FWADC) were near the daily capacity, with average daily application rates of 38.8 m^3 for the Hercules and 14.8 m^3 for the FWADC. The vessels applied on average 6.3 m^3 per day (63% of the daily capacity of 10 m^3 per day), with reduced efficiencies primarily being the result of long times required to cruise from Port Hedland to the response site that reduced the amount of daylight hours available for dispersant application. The total volume of dispersant applied throughout the SDA response was 13,861 m^3.

The SDA response yields significant reductions in instantaneous surface oil loads of up to ~15,000 tonnes that were concomitant with approximately equal increases in the entrained oil mass (Figure 51).

The reduction in surface oil loads yields significant benefits to the shoreline loading. The accumulated shoreline load reduces from 5,127 tonnes for the unmitigated simulation to 3,830 tonnes for the SDA simulation (Table 38), indicating that 1,297 tonnes of oil were prevented from arriving at shorelines as a result of the response. At the moderate threshold (100 g/m^2), significant reductions in peak oil loads were also predicted at all contacted receptors (with the exception of Bedout Island which had a negligible change in peak oil load). A total peak loading of 2,091 tonnes was predicted across all shorelines, which was reduced from 2,940 tonnes for the unmitigated simulation.

4.2.4.2.2 SDA Response without the 25 km exclusion zone

For the SDA response that did not incorporate the 25 km exclusion zone, the total daily dispersant application capacity for each response unit is 15 m^3 for FWADC (5 sorties per day, 3 m^3 dispersant tank), 40 m^3 for the Hercules (4 sorties, 10 m^3 dispersant tank) and 10 m^3 for vessels (1 sortie, 10 m^3 dispersant tank). Given the operational constraints (Section 3.5), the simulated dispersant application rates for the response aircraft (Hercules and FWADC) were near the daily capacity, with average daily application rates of 39.9 m^3 for the Hercules and 14.9 m^3 for the FWADC. The vessels applied on average 7.4 m^3 per day (74% of the daily capacity of 10 m^3 per day), with reduced efficiencies primarily being the result of long times required to cruise from Port Hedland to the response site that reduced the amount of daylight hours available for dispersant application. The total volume of dispersant applied throughout the SDA response was 14,322 m^3. The higher dispersant volumes applied for the scenario compared to the SDA scenario that incorporated the 25 km exclusion zone are the result of greater availability of surface oil in close proximity to the well that meets the response thresholds (>50 um thickness).

In general, the SDA without the exclusion zone yields similar surface oil and entrained oil masses to the SDA response that incorporated the exclusion zone (Figure 51), though in some instances the maintenance of the exclusion zone yielded greater reductions in surface oil by an additional ~5,000 tonnes. Further, a higher volume of chemical dispersant is required without the exclusion zone to achieve a similar (and slightly less effective) outcome.

The shoreline load reductions predicted for the SDA response without the exclusion zone were significant, but less than those with the exclusion zone. Accumulated shoreline load was predicted to decrease from 5,127 tonnes for the unmitigated simulation to 4,051 tonnes for SDA without the exclusion zone (Table 38) (i.e. prevention of 1,076 tonnes of oil shoreline arrival in comparison with 1,297 tonnes with the exclusion zone). At the moderate threshold (100 g/m^2) a total peak loading of 2,323 tonnes was predicted across all shorelines, which was lower than the 2,940 tonnes for the unmitigated simulation, but higher than the 2,091 tonnes for the exclusion zone scenario.

Overall, these results indicate that incorporating an exclusion zone around the well for the SDA response strategy is effective to allow evaporation to occur prior to application of chemical dispersants onto the surface slick. This also reduces the amount of dispersant required and provides environmental benefits in the form of reduced shoreline loads.

4.2.5 Apus Base Case Surface LOWC Scenario #5

Stochastic realisation 5 of the Apus Base Case Surface LOWC scenario resulted in the earliest arrival time of shoreline accumulation above the low (10 g/m^2) and moderate (100 g/m^2) thresholds of 2 days (to Bedout Island).

The unmitigated simulation of this realisation resulted in a surface slick exceeding 10 µm thickness that extended up to ~500 km from the release location (Figure 58). Total submerged oil exceeding 100 ppb extended up to ~900 km, while dissolved hydrocarbons exceeding 50 ppb were limited in spatial extent to within ~200 km from the release location (Figure 59). Shoreline loading greater than 10 and 100 g/m^2 extended up to ~900 km to the east of the release site (Figure 59).

Shoreline accumulation for this realisation above both thresholds (10 g/m^2 and 100 g/m^2) began during day 2 at Bedout Island, with significant shoreline loading events continuing at a range of shoreline receptors until day 106. A time-series of shoreline accumulation impacts during this realisation is presented in Figure 60 (for 10 g/m^2 and 100 g/m^2), while summarised shoreline loading predictions are displayed in Table 39 and Table 40 for 10 and 100 g/m^2, respectively. The following key shoreline impacts are predicted at the moderate threshold (100 g/m^2):

- Moderately high instantaneous peak loads of 140-317 tonnes were predicted at Port Hedland-Eighty Mile Beach, Dampier Archipelago, Montebello Islands, Barrow Island, Southern Islands Coast, Muiron Islands and Ningaloo Coast North. With the exception of Port Hedland-Eighty Mile Beach, which reached a peak load of 257 tones on day 4, the other locations received shoreline loading after day 60, with peak loading occurring between days 75-110.
- Lower, but significant peak shoreline loads were also predicted at Thevenard Islands (56 tonnes on day 106), Ningaloo Coast South (62 tonnes on day 110), Shark Bay – Coast Outer (17 tonnes on day 101) and Bedout Island (33 tonnes on day 2).
- Across all shorelines combined, a peak oil loading of 1,292 tonnes occurred during day 106, with a maximum oiled shoreline length of 496 km.

The predicted hydrocarbon weathering (i.e. mass balance partitioning) for the specific met-ocean conditions encountered during the deterministic simulation is presented in Figure 58, and summarised as follows:

- Evaporation is the primary weathering mechanism with evaporated oil accounting for ~75% of the total oil mass by day 90.
- Oil decay (i.e. biodegradation) accounts for an additional ~22% of the oil by the end of the simulation (day 112).
- Several large wind-driven entrainment events occurred throughout the simulation resulting in increases in the mass of entrained droplets that were concomitant with decreases in the mass of surface oil. For this surface discharge, entrained droplets typically accounted for ~10-20% of the total oil mass throughout the duration of the discharge (i.e. the first 77 days), while surface oil was typically 1-20% of all oil during this period.

4.2.6 Apus Base Case Surface LOWC Scenario #9

Stochastic realisation 9 of the Apus Base Case Surface LOWC scenario resulted in the maximum length of shoreline with accumulated oil above the low (10 g/m^2) threshold of 523 km, while also producing the maximum length for accumulated oil above the moderate (100 g/m^2) threshold of 500 km.

The unmitigated simulation of this realisation resulted in a surface slick exceeding 10 µm thickness that extended up to ~500 km from the release location (Figure 61). Total submerged oil exceeding 100 ppb extended up to ~850 km, while dissolved hydrocarbons exceeding 50 ppb were limited in spatial extent to within ~200 km from the release location (Figure 62). Shoreline loading greater than 10 and 100 g/m^2 extended up to ~700 km to the east of the release site (Figure 62).

Shoreline accumulation for this realisation above both thresholds (10 g/m^2 and 100 g/m^2) began during day 28 at Dampier Archipelago, with significant shoreline loading events continuing at a range of shoreline receptors until day 89. A time-series of shoreline accumulation impacts during this realisation is presented in Figure 63 (for 10 g/m^2 and 100 g/m^2), while summarised shoreline loading predictions are displayed in Table 41 and Table 42 for 10 and 100 g/m^2, respectively. The following key shoreline impacts are predicted at the moderate threshold (100 g/m^2):

– Moderately high instantaneous peak loads of 190-443 tonnes were predicted at Dampier Archipelago, Montebello Islands, Barrow Island, Southern Islands Coast, Muiron Islands and Ningaloo Coast North. Shoreline loading events at these receptors generally occurred between days 28 to 89.
– Lower, but significant peak shoreline loads were also predicted at Northern Islands Coast (35 tonnes on day 64), Lowendal Islands (27 tonnes on day 62), Middle Islands Coast (3 tonnes on day 60), Thevenard Islands (67 tonnes on day 66), Ningaloo Coast South (21 tonnes on day 93) and Shark Bay – Coast Outer (13 tonnes on day 103).
– Across all shorelines combined, a peak oil loading of 1,790 tonnes occurred during day 89, with a maximum oiled shoreline length of 449 km.

Notably for this simulation, the deterministic predictions of oiled shoreline lengths at 10 g/m^2 (591 km) and 100 g/m^2 (449 km) are longer and shorter, respectively, than the stochastic outcomes of 523 km (10 g/m^2) and 500 km (100 g/m^2). As outlined in section 4.2.2, the increased length for the low threshold (10 g/m^2) is due to the inclusion of shoreline washing in the deterministic simulation which remobilises portions of stranded oil, allowing shoreline stranding to occur across longer stretches of shoreline. The reduction for the moderate threshold (100 g/m^2) is due to the weathering processes that occur on stranded oil in the deterministic simulation (that aren't accounted for by the stochastic 'accumulated' statistic), that cause several model cells to no longer exceed the threshold, thereby reducing the length of contacted shoreline reported for the threshold.

The predicted hydrocarbon weathering (i.e. mass balance partitioning) for the specific met-ocean conditions encountered during the deterministic simulation is presented in Figure 61, and summarised as follows:

– Evaporation is the primary weathering mechanism with evaporated oil accounting for ~75% of the total oil mass by day 90.
– Oil decay (i.e. biodegradation) accounts for an additional ~22% of the oil by the end of the simulation (day 112).
– Several large wind-driven entrainment events occurred throughout the simulation resulting in increases in the mass of entrained droplets that were concomitant with decreases in the mass of surface oil. For this surface discharge, entrained droplets typically accounted for ~10-20% of the total oil mass throughout the duration of the discharge (i.e. the first 77 days), while surface oil was typically 1-20% of all oil during this period.

4.2.7 Apus Base Case Surface LOWC Scenario #101

Stochastic realisation 101 of the Apus Base Case Surface LOWC scenario resulted in the highest mass of surface oil exceeding the high (response) threshold (50 g/m^2).

The unmitigated simulation of this realisation resulted in a surface slick exceeding 10 µm thickness that extended up to ~400 km from the release location, while the portion of the slick that exceeded 50 µm occurred up to ~150 km from the release location (Figure 66). Total submerged oil exceeding 100 ppb extended up to ~500 km, while dissolved hydrocarbons exceeding 50 ppb were limited in spatial extent to within ~125 km from the release location (Figure 66). Shoreline loading greater than 100 g/m^2 extended up to ~400 km to the east of the release site (Figure 62).

The mass of surface oil exceeding 50 µm thickness remains high throughout the initial 77 days of the simulation while oil is being released (Figure 65). The surface oil mass at the high threshold reaches 60,000 tonnes during day 9, and generally remains between 30,000 and 90,000 tonnes until day 72. A peak surface oil mass of 89,700 tonnes occurred during day 71. This indicates the maximum instantaneous mass of surface oil that could potentially by targeted by mitigative actions such as surface dispersant application or containment and recovery, and can be used to inform peak resource requirements for these responses.

Shoreline accumulation for this realisation above the moderate threshold (100 g/m^2) began during day 29 at Dampier Archipelago, with significant shoreline loading events continuing at a range of shoreline receptors until day 108. A time-series of shoreline accumulation impacts during this realisation is presented in Figure 67, while summarised shoreline loading predictions are displayed in Table 43. The following key shoreline impacts are predicted at the moderate threshold (100 g/m^2):

- A moderately high instantaneous peak load of 190 tonnes was predicted at Dampier Archipelago on day 108.
- Lower, but significant peak shoreline loads were also predicted at Imperieuse Reef (11 tonnes on day 98), Montebello Islands (9 tonnes on day 109) and Bedout Island (30 tonnes on day 83).
- Across all shorelines combined, a peak oil loading of 225 tonnes occurred during day 108, with a maximum oiled shoreline length of 92 km.

The predicted hydrocarbon weathering (i.e. mass balance partitioning) for the specific met-ocean conditions encountered during the deterministic simulation is presented in Figure 61, and summarised as follows:

- Evaporation is the primary weathering mechanism with evaporated oil accounting for ~80% of the total oil mass by the end of the simulation (day 112).
- Oil decay (i.e. biodegradation) accounts for the remaining ~20% of the oil by the end of the simulation (day 112).
- The surface slick for this scenario is relatively persistent, though several small wind-driven entrainment events occurred throughout the simulation resulting in increases in the mass of entrained droplets that were concomitant with decreases in the mass of surface oil. For this surface discharge, entrained droplets typically accounted for ~0-20% of the total oil mass throughout the duration of the discharge (i.e. the first 77 days), while surface oil was typically ~0-40% of all oil during this period, and was consistently 10-40% of the oil during the first 50 days.

Scott Reef South (Emergent)	3	Scott Reef is a large, emergent shelf atoll. South Reef is a crescent shaped reef 17 km across The place is regionally significant both because of its high representation of species not found in coastal waters off Western Australia and for the unusual nature of its fauna which has affinities with the oceanic reef habitats of the Indo-West Pacific as well as the reefs of the Indonesian region ***Threatened/Migratory Fauna*** Marine fauna Invertebrates Cetacean migration Seasnakes Nesting and foraging green and hawksbill turtles Finfish and rays Whale sharks High fish diversity (>550 species of fish recorded) and 5 endemic species ***Physical Environment/ Habitat*** Coral reef Seagrass Non-coral benthic habitats High coral and fish diversity Sandy beaches ***Protected area*** Key Ecological Feature (Seringapatam Reef and Commonwealth Waters in the Scott Reef Complex)	**Probability of contact by floating oil at 10 g/m²**	**(%)**	NC	NC	NC	NC	Threatened/Migratory Fauna Physical Environment/ Habitat Protected Areas Socio-Economic Receptors	II II II II	II

1 INTRODUCTION

Santos is proposing to develop the Dorado oil field, located in the Bedout basin, approximately 150 km north of Port Hedland. Surface components of the proposed development will comprise an unmanned wellhead platform and a Floating Production, Storage and Offloading facility (FPSO).

Light emissions have the potential to impact biological receptors, thus CDM Smith has engaged Pendoley Environmental (PENV) on behalf of Santos to undertake modelling of these emissions to help inform an impact assessment. The FPSO presents the greatest source of light emissions based on the size of the facility and that it will be permanently manned and operational while infield. Light emissions from the wellhead platform will be restricted to navigational lights only, unless during specific, short term activities such as well intervention campaigns. For this reason, lighting of the wellhead platform was not considered further.

2 METHODOLOGY

Light modelling was undertaken for two scenarios; flaring (all lights, plus flare) and non-flaring (lights only), to predict the extent of biologically relevant light spill. The facility’s lighting design and luminaire specifications were applied to the ILLUMINA Artificial Light At Night (ALAN) model (Aube *et al*. 2005). The ILLUMINA model is a three-dimensional model that accounts for both line of sight and atmospheric scattering, allowing the attenuation of light over distance and extent of light glow to be modelled. The reader is directed to Aube *et al*. (2005) for details of equations and model parameterisation.

Unlike a simple line of sight model based on the inverse square law formula, this is a more sophisticated model which allows individual light sources (i.e. individual luminaires) to be placed within the area of interest (as opposed to assuming a single large light point source for the entire FPSO). The model input parameters also include project specific details about light type, spectral distribution, height and orientation of individual luminaires, including any shielding, which substantially increases the model precision and accuracy.

2.1 Model Inputs

Information regarding the light inventory for the non-flaring scenario was provided by Santos and is shown in **Table 1**. This includes:

- number of each type of light
- spectral output of light type (**Figure 1**)
- angular distribution of light (shielding)
- lumen output of each type of light
- elevation (above sea level) of each light

Table 1: Lighting inventory for non-flaring scenario

Light type	Quantity	Power (lm)	Height (m)	Spectrum/CCT	Shielding

Series 6525 LED Floodlight	5	21000	11		
Series 6525 LED Floodlight	5	21000	47		

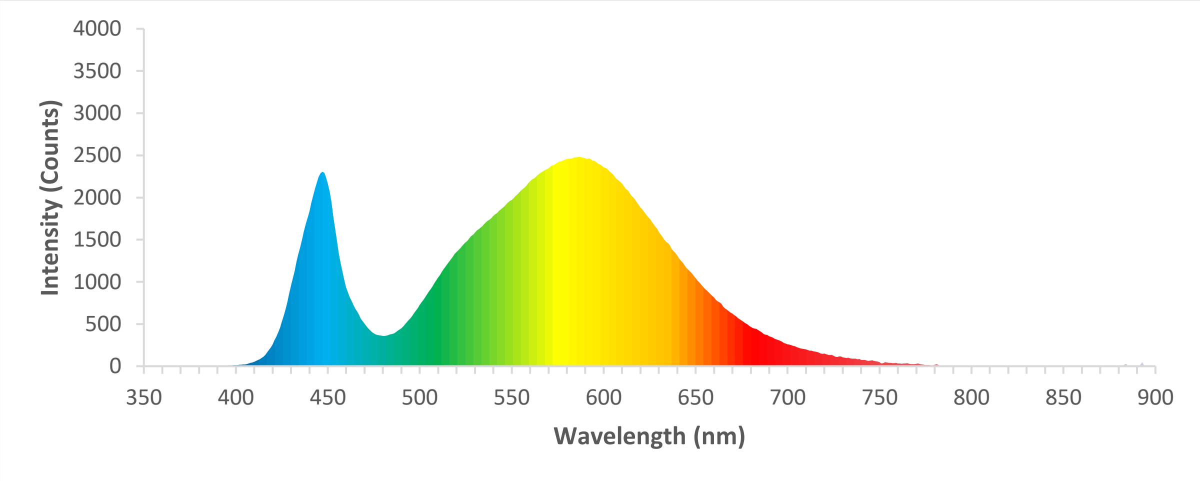

Figure 1: Spectral power distribution of a 4000K LED.

The second scenario with flaring, is more complex. There is currently no published information on the lumen/radiance output of gas flares used in industry. While PENV was provided with estimated flow rates for the flare, methodology for deriving radiance output from flow rates is unproven and results could vary significantly based on gas composition. An alternative route was taken by using VIIRS-DNB4 (satellite) radiance data of known maintenance (i.e. worst case) flaring events at existing LNG facilities to obtain a base radiance value for a flare before applying to the model. As marine turtles typically have a field of view focused towards the horizon, satellite data measures of upward-radiance and would not normally be suitable for determining horizontal emissions. However, in this case the flare is treated as a spherical emission source and thus our upward-radiance measured values can be applied to a horizontal perspective. This approach was considered more reliable than calculations based on flow rate. Based off this data, the value for the output radiance of the flare was estimated to be 500 $\mu W/m^2/sr$ at a height of 110 m.

Surface reflectance and elevation values are incorporated into the model from aerial imagery supplied by the National Aeronautics and Space Administration (NASA) Earthdata and the National Oceanic and Atmospheric Administration (NOAA) (NASA, 2020; NOAA, 2020) as per the methodology outlined in Aube *et al*. (2005).

Both scenarios assume that all lights emit as a perfect sphere and the FPSO structure itself is absent, thereby having no influence on reflection/absorption of light. While light intensity inputs are provided as lumens (light emission), model outputs are provided in radiance ($W/m^2/sr$, where W = watts, m^2 =meters squared and sr = steradian), which describes the light received in a specific area.

2.2 Interpretation and Limitations

In the absence of any published or generally accepted units of measurement, or scale, for measuring the impact of ALAN on marine turtles, moonlight was selected as a proxy and the light model output (radiance, units of $W/m^2/sr$) was converted to units of full moon equivalents in an attempt to give the radiance output some biological relevance and to aid interpretation in an environmental impact assessment context. The reasoning used was:

- the range of moon brightness across a whole lunar cycle is a realistic scale representative of the ambient light levels that turtle eyes are adapted to. At the lower end of the scale the radiant output is equivalent to no light in the sky while the upper limit is greater than the radiance from a single full moon and was selected to try to account for the increase in radiance levels that would occur if the light was reflected from clouds (recognizing that cloudy conditions are not the norm for this site). Extending the scale beyond this limit was deemed unnecessary.
- the scale for the units "the proportion of radiance of one full moon" was derived from the logarithmic nature of light decay with distance (a function of the inverse square law), e.g. the scale of <0.01, 0.01 – 0.1, 0.1 – 1, 1 – 10 represents a range of radiant brightness from a minimum of <0.01 full moon (so essentially a new moon) to a maximum radiant brightness of the equivalent to 10 full moons.

While the behavioural response of marine turtles to light is relatively well understood (see Witherington and Martin (2003) for review), there is currently no agreed upon intensity limits for determining what the impact of a given light might be. Studies suggest that hatchling turtles are the most vulnerable life stage to potential impacts from artificial light (e.g. Witherington, 1992). A large range of factors influence the visibility and impact of light on hatchlings including light intensity, visibility (a function of lamp orientation and shielding), spectral power distribution (wavelength and colour), atmospheric scattering, cloud reflectance, spatial extent of sky glow, duration of exposure, horizon elevation, lunar phase, hatchling swimming speeds, tide and current speeds and flow direction etc. Using the scale of light radiance derived from the calculated decrease in light intensity with distance (proportion radiance of a full moon). Due to the increased vulnerability of hatchlings, potential impact criteria developed for hatchlings are considered inclusive of other life stages (including internesting and nesting females). Together with our extensive SME experience observing marine turtles and their response to both onshore and offshore construction light in field settings, we have proposed conservative, potential impact criteria for marine turtles based on radiance thresholds relative to moon radiance, as shown in **Table 2**.

Although the potential effects of ALAN on other marine fauna, such as seabirds or migratory shorebirds, is gaining more recognition, the vulnerability of individuals to negative impacts of

ALAN is highly species specific and can vary depending on the life stage or behaviour being undertaken at the time (see Commonwealth of Australia (2020) for review). Accordingly, while presenting radiance as a measure relative to that of a full moon is biological relevant to other marine taxa, potential impact criteria could not be defined.

Table 2: Artificial light impact potential criteria (marine turtles)

Proportion of radiance of a full moon*	Impact potential to marine turtles
> 1	Light or light glow visible and impact likely, represents a very bright light greater than a full moon. This light radiance will override the moderating influence of the ambient full moon at the time of exposure.
0.1 - 1	Light or light glow visible and behavioural impact possible, depending on ambient moon phase at the time of exposure, which will influence the visibility of the artificial light sources, equivalent to the light output. Artificial lights will be more visible to marine turtles under a first quarter moon than under a full moon.
0.01 - 0.1	Light or light glow visible but behavioural impact unlikely (i.e. not biologically relevant). Equivalent to the light output from the first quarter moon to new moon.
< 0.01	Light or light glow is considered ambient and no impact expected, equivalent to a new moon

*Where 1 equals the radiance of one full moon and 0.01 equals 100th the radiance of one full moon

3 RESULTS

Results from the ILLUMINA model undertaken for the FPSO facility located at coordinates 19.04694 S, 118.74333 E are presented in **Table 3** and **Figure 3**.

When applying the potential impact criteria in **Table 2**, the results show that, at ~17.7 km from the source, radiance has reduced to ambient in the non-flaring scenario. At distances between ~ 5.5 km and ~17.7 km from the source, radiance is equivalent to between 0.1 and 0.01 radiance of a full moon and, therefore, light may be visible but unlikely to result in a behavioural impact to marine turtles. Impacts to marine turtles may occur within ~5.5 km of the FPSO, depending on moon phase, and are more likely within ~1.8 km of the FPSO, when radiance is equivalent to that of one full moon.

In the flaring scenario, the flare is no longer directly visible at 42.4 km, when the flare drops below the horizon. At this distance, the radiance is equivalent to 0.25 full moons. Thus, impacts to marine turtles may occur at any point within this distance, becoming more likely within 20.7 km. The nearest shorelines are Bedout and Turtle Island, at approximately 70 km and 95 km from the facility respectively. No direct light will be visible from beaches on these islands, as shown in **Figure** 2**.**

Table 3: Distance of equivalent moon radiances for the non-flaring scenario

Proportion of radiance of a full moon*	**Distance from FPSO at which equivalent moon radiance is reached (m)**	
	Non-Flaring	**Flaring**
1000		450
100	180	1690
10	550	6260
1	1790	20700
0.1	5539	
0.01	17740	

*Where 1 equals the radiance of one full moon and 0.01 equals 100th the radiance of one full moon

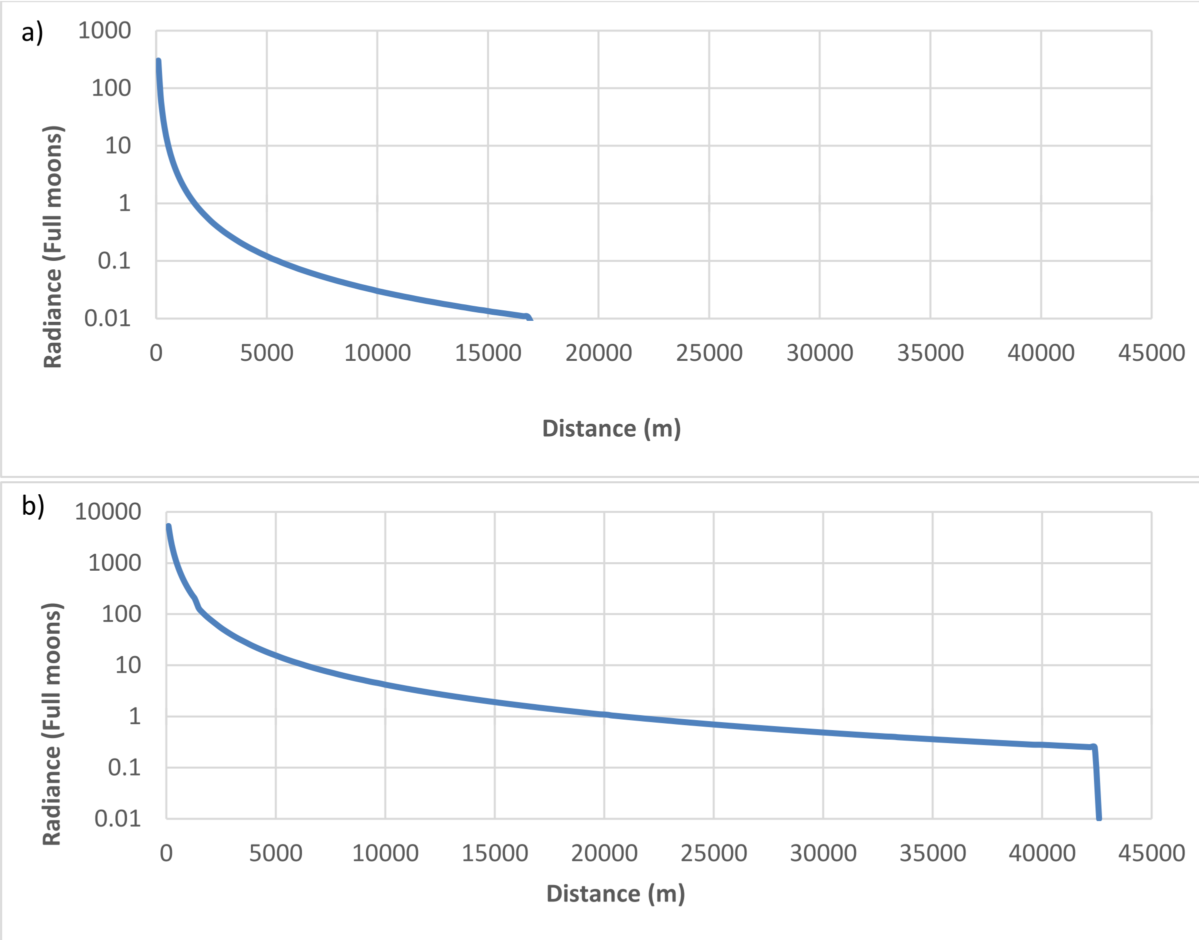

Figure 3: Radiance of light sources with distance from the FPSO facility. a) Non-flaring scenario. b) Flaring scenario. The sudden drop off in (b) at 42,400 m represents the distance at which the flare drops below the horizon and is no longer visible.

4 SUMMARY

Model outputs are in radiance ($W/m^2/sr$) and presented as a proportion of the radiance of a full moon as a realistic scale representative of the natural conditions experienced by a marine fauna receptor in the field and to provide biological context.

The distance from source at which a given level of radiance was reached (reported as proportion of radiance of a full moon) was greater for the flaring scenario, as expected. Light emissions were predicted to reduce to ambient levels (0.01, or 1%, radiance of a full moon) at 17.7 km for the non-flaring scenario, and do not reach ambient in the flaring scenario before the flare disappears from the observer’s view, instead reaching a radiance equivalent to a quarter moon. The closest shorelines are Bedout Island (70 km) and Turtle Island (95 km), from which no direct light will be visible.

Executive Summary

Santos WA Northwest Pty Ltd (referred to herein as Santos) are proposing to develop the Dorado oil field, on the North West Shelf of Western Australia. Referred to as the Dorado Development, the project will include a Well Head Platform (WHP) and a Floating Production Storage and Offloading (FPSO) facility. The FPSO will have a turret mooring system that will be stabilised using mooring lines secured to the seabed by piles. This modelling study provides the basis to assess the impacts of noise from these activities on marine mammals, sea turtles, fish (adults, larvae, eggs), plankton, sponges and corals.

This modelling study considered the following representative activities to inform the impact assessment:

- Installing a single subsea WHP jacket pile per day through impact piling.
- Installing a single subsea FPSO mooring pile per day through impact piling.
- Vertical Seismic Profiling (VSP) from a crane suspended source during drilling operations.
- FPSO operational noise for an FPSO under normal operating conditions.
- An Offshore Support Vessel (OSV) supporting offtake operations
- FPSO operational noise during offtake, represented by:
  - The FPSO under dynamic positioning (DP).
  - The FPSO under DP, with a noiseless condensate tanker, and the OSV supporting the offtake.

Pile Installation

The predicted distances to all per-strike isopleths (contours of equal sound level) are farthest from the piles at the start of piling, when the most of the pile is in the water column, and smallest at the end of piling, when most of the pile is buried in the sediment. This is despite the increased frictional resistance of sediments and stronger stress-wave reflections at the pile toe at later stages of insertion.

For exposure criteria based on cumulative metrics, the ranges must be considered in the context of the duration of operations. Given that one pile will be driven per day at each location, the corresponding sound level is denoted as the accumulated sound exposure level over 24 h (SEL_{24h}); the effective time estimates for driving piles, however, are 1.6 h for the WHP jacket piles and 4.7 h for the FPSO anchor piles. A single subsea hammer (MHU 600T) was modelled for driven piles at each location.

SEL_{24h} is a cumulative metric that reflects the dosimetric impact of noise levels within the pile driving period, based on the assumption that an animal is consistently exposed to such noise levels at a fixed position. The radii that correspond to SEL_{24h} typically represent an unlikely worst-case scenario for SEL-based exposure since, more realistically, marine fauna such as mammals and fish would not stay in the same location or at the same distance from a sound source for an extended period. Therefore, a reported radius for SEL_{24h} criteria does not mean that any animal travelling within this radius from the source *will* be injured, but rather that it *could* be injured if it remained within that range for the entire duration of the pile driving.

Ranges to Exposure Thresholds

The analysis considered multiple effects criteria commonly used in pile driving noise assessments. Key results of the acoustic modelling are summarised below.

Marine Mammals

- United States National Oceanic and Atmospheric Administration (NOAA) (2019) acoustic threshold for behavioural effects in cetaceans: Pile driving impulse sounds are predicted to exceed the SPL threshold of 160 dB re 1 µPa for behavioural effects of marine mammals between

3.4–5.4 km, the minimum and maximum distances depending on the depth of penetration and type of pile being driven.

- Southall et al. (2019) criteria for marine mammal Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): The assessment considers both metrics within the criteria (peak pressure level (PK) and SEL)), with SEL assessed here for a single pile within a 24 h period, i.e., a single pile per day. The metric with the longest distance must be applied, and these maximum distances along with the relevant metric are summarised in Table 1.

Table 1. Maximum-over-depth distances (in km) to marine mammal PTS and TTS thresholds for pile driving from Southall et al. (2019).

Hearing group	WHP jacket pile		FPSO anchor pile	
	Metric associated with longest distance to injury criteria	R_{max} (km)	Metric associated with longest distance to injury criteria	R_{max} (km)
PTS				
Low-frequency cetaceans	SEL_{24h}	5.29	SEL_{24h}	5.84
High-frequency cetaceans	SEL_{24h}	–	SEL_{24h}	0.03
Very-high-frequency cetaceans	PK	0.55	SEL_{24h}	1.04
TTS				
Low-frequency cetaceans	SEL_{24h}	22.6	SEL_{24h}	28.2
High-frequency cetaceans	SEL_{24h}	0.29	SEL_{24h}	0.36
Very-high-frequency cetaceans	SEL_{24h}	2.78	SEL_{24h}	4.27

For the SEL_{24h} criteria, the model does not account for shutdowns.
A dash indicates the threshold was not reached within the limits of the modelling resolution (20 m).

Sea Turtles

- U.S National Marine Fisheries Service (NMFS) criterion for behavioural response (SPL of 166 dB re 1 µPa) and a criterion for increased behavioural disturbance (SPL of 175 dB re 1 µPa) (Moein et al. 1995, McCauley et al. 2000b, 2000a): The maximum distances to the two criteria considered are summarised in Table 2.
- Finneran et al. (2017) criteria for sea turtle Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): The assessment considers both metrics within the criteria (PK and SEL), with SEL assessed here for a single pile within a 24 h period, i.e., a single pile per day. The metric with the longest distance must be applied, and these maximum distances along with the relevant metric are summarised in Table 3.

Table 2. Maximum (R_{max}) horizontal distances (in km) from the pile to modelled maximum-over-depth turtle behavioural response thresholds, maximum across all three penetration depths.

Threshold	WHP jacket pile	FPSO anchor pile
	R_{max} (km)	R_{max} (km)
Turtle behaviour, SPL: 166 dB re 1 µPa (NSF 2011)	3.51	2.91
Turtle behaviour, SPL: 175 dB re 1 µPa (McCauley et al. 2000b, McCauley et al. 2000a)	1.39	1.07

Table 3. Maximum-over-depth distances (in km) from the pile to turtle PTS and TTS thresholds (Finneran et al. 2017).

Threshold	WHP jacket pile		FPSO anchor pile	
	Metric associated with longest distance to injury criteria	R_{max} (km)	Metric associated with longest distance to injury criteria	R_{max} (km)
PTS	SEL_{24h}	0.72	SEL_{24h}	0.68
TTS	SEL_{24h}	4.11	SEL_{24h}	3.98

For the SEL_{24h} criteria, the model does not account for shutdowns.

Fish, Fish Eggs, and Fish Larvae

- This study assessed the ranges for quantitative criteria from Popper et al. (2014) associated with mortality and potential mortal injury and impairment in the following:
    - Fish without a swim bladder (also appropriate for sharks in the absence of other information)
    - Fish with a swim bladder not used for hearing
    - Fish that use their swim bladders for hearing
    - Fish eggs, and fish larvae
- The maximum distance from pile driving at which sound levels exceeded mortality and potential mortal injury (SEL_{24h} metric) for the most sensitive fish groups is 560 m for the WHP jacket pile and 520 m for the FPSO anchor pile.
- Fish (including sharks) could experience TTS (SEL_{24h} metric) from the proposed pile driving activity. It is predicted that this will occur within 5.59 km for the WHP jacket pile and 5.88 km for the FPSO anchor pile.

Vertical Seismic Profiling

The modelling scenarios for VSP considered a single 750 in^3 array suspended at 5 m from the sea surface at the WHP. Modelling assessed both individual impulses and multiple impulses within a 24 h period to determine SEL_{24h}.

The analysis considered multiple effects criteria commonly used in seismic survey noise assessments. Key results of the acoustic modelling are summarised below.

Marine Mammals

- NOAA (2019) acoustic threshold for behavioural response in marine mammals: The maximum distance to the SPL threshold of 160 dB re 1 µPa was 2.42 km from the centre of the VSP array.
- Southall et al. (2019) criteria for marine mammal Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): The SEL_{24h} threshold distance considers multiple impulses within a 24 h period, ranging from 1 to 300. The applicable metric from the criteria, associated with the longest distance associated with either metric, depends upon the number of impulses within the 24 h. The ranges presented are based upon a maximum of 300 impulses. A reported radius for SEL_{24h} criteria does not mean that marine mammals travelling within this radius of the source will be injured, but rather that an animal could be exposed to the sound level associated with effect (either PTS or TTS) if it remained in that location for either 24 hours or the duration of the activity if less.
    - For low-frequency cetaceans, the PTS and TTS thresholds associated with the PK metric were predicted to be less than 20 m from the centre of the acoustic source; the PTS and TTS ranges were therefore determined by SEL_{24h}, with the maximum distances reached at 470 m for PTS and 3.1 km for TTS.
    - PTS and TTS are not predicted to occur for high-frequency cetaceans.

- For PTS in very high-frequency cetaceans, the PK metric was always associated with the longest range (63 m), as was the case for TTS (241 m).

Sea Turtles

- Finneran et al. (2017) criteria for sea turtle Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): The SEL_{24h} threshold distance considers multiple impulses within a 24 h period, ranging from 1 to 300. Similarly to marine mammals, the reported radii for SEL_{24h} criteria do not mean that sea turtles travelling within this distance of the source will be injured, but rather that an animal could be exposed to the sound level associated with effect (TTS) if it remained in that location for either 24 h or the duration of the activity if less.
  - Within the range of considered impulses (1–300), the PTS threshold was first exceeded at a maximum distance of 30 m when considering the SEL_{24h} criteria for 150 impulses. The PK threshold may be exceeded at distances less than 20 m from the centre of the acoustic source, if at all.
  - While the TTS criterion due to the PK metric was not exceeded, depending upon the number of impulses the TTS SEL_{24h} criterion may be exceeded at a maximum distance of 380 m for 300 impulses.
- Behavioural effects in sea turtles: The maximum distance to the NMFS criterion (NSF 2011) for behavioural effects in sea turtles of 166 dB re 1 µPa (SPL) is 1.22 km, and the maximum distance to the McCauley et al. (2000b), McCauley et al. (2000a) disturbance criterion of 175 dB re 1 µPa (SPL) is 0.38 km.

Fish, Fish Eggs, and Fish Larvae

- This modelling study assessed the ranges for quantitative criteria based on Popper et al. (2014) and considered both PK (seafloor and water column) and SEL_{24h} metrics associated with mortality and potential mortal injury and with impairment in the groups listed in the piling section:
- The distance from pile driving at which sound levels exceeded the limit for mortality and potential mortal injury for the most sensitive fish groups was 37 m (PK metric).
- Within the range of considered impulses (1–300), the distance to the threshold for the SEL_{24h} metric for injury was first reached at a maximum distance of 50 m for 200 impulses.
- Sound levels at the seafloor do not exceed any of the fish criteria.

Sponges and Coral

To assist with assessing the potential effects on these receptors, the following have been determined:

- Sponges and coral: The PK sound level at the seafloor directly underneath the VSP source was estimated at both modelling sites and did not reach the sound level of 226 dB re 1 µPa PK for sponges and corals (Heyward et al. 2018);

Vessel Operations

The modelled scenarios for vessels consider the following sources:

- An FPSO facility 370 m long and 67 m wide:
  - under typical operations, with no thrusters and no offtake, only topsides equipment; and
  - under dynamic positioning representative of typical operational loads during moderate weather conditions to inform an offtake scenario.
- A representative Offshore Support Vessel (OSV), namely a dynamic positioning Class 2 (DP2) vessel within 700 m of the FPSO under dynamic positioning representative of typical operational loads during moderate weather conditions while assisting FPSO offtake into a noiseless condensate tanker.

The analysis considered multiple effects criteria commonly used in seismic survey noise assessments. Key results of the acoustic modelling are summarised below.

Marine Mammals

- The results for the Southall et al. (2019) criteria applied for marine mammal PTS and TTS for vessels were assessed for a 24 h period with the maximum distances to PTS summarised in Table 4.
- The maximum distances to the NOAA (2019) marine mammal behavioural response criterion of 120 dB re 1 µPa (SPL) are summarised in Table 5.

Table 4. Maximum (R_{max}) horizontal distances (km) from the vessels to modelled maximum-over-depth marine mammal PTS threshold from Southall et al. (2019).

Hearing group	Threshold for PTS, SEL_{24h} (dB re 1 µPa²·s)	Distance R_{max} (km)			
		FPSO under DP	FPSO without DP	OSV	Offtake operations*
Low-frequency cetaceans	199	0.07	–	0.03	0.08
High-frequency cetaceans	198	–	–	–	–
Very-high-frequency cetaceans	173	0.21	–	0.05	0.21

A dash indicates the threshold was not reached within the limits of the modelling resolution (20 m).
* Radial distances for isopleths/thresholds that envelope the FPSO and OSV were reported from the mid-point between the FPSO and the OSV modelled sites. Otherwise radial distances were reported from the FPSO modelled location.

Table 5. Summary of maximum marine mammal behavioural disturbance distances for vessels

Threshold	Distance R_{max} (km)			
	FPSO under DP	FPSO without DP	OSV	Offtake operations*
Marine mammal behaviour, SPL: 120 dB re 1 µPa (NOAA 2019)	10.4	1.49	4.57	11.0

* Radial distances for isopleths/thresholds that envelope the FPSO and OSV were reported from the mid-point between the FPSO and the OSV modelled sites. Otherwise radial distances were reported from the FPSO modelled location.

Sea Turtles

- Finneran et al. (2017) criteria for sea turtle Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): TTS is not predicted to occur for the FPSO without DP within the modelling resolution of 20 m, and only at distances of up to 50 m for the FPSO under DP and offtake operations. PTS is not predicted to occur. Behaviour is assessed through the relative risk criteria.

Fish

- Popper et al. (2014): Sound produced by the vessel operations could cause physiological effects and recoverable injury to some fish species, but only if the animals are in very close proximity to the sound sources—within a planar distance of 30 m, for 48 h. Temporary impairment due to TTS could occur at similar short distances if a fish remained at the same location within the sound field for a duration exceeding 12 h.

1. Introduction

JASCO Applied Sciences (JASCO) performed a modelling study of underwater sound levels associated with the development of the Dorado oil field, on the North West Shelf of Western Australia. The Dorado Development will include a Well Head Platform (WHP) and a Floating Production Storage and Offloading (FPSO) facility. The FPSO will have a turret mooring system that will be stabilised using mooring lines secured to the seabed by piles. The modelling study considered the installation of piles for the WHP and FPSO anchors, vertical seismic profiling (VSP) during drilling operations, and operation of the FPSO, including offload activities.

This study specifically assessed distances from the considered operations to where underwater sound levels reached thresholds corresponding to various levels of impact to marine fauna. The fauna considered in this study included marine mammals, sea turtles, fish (including fish eggs and larvae), plankton, sponges and corals. Due to the variety of species considered, there are several different thresholds for evaluating effects, including: mortality, injury, temporary reduction in hearing sensitivity, and behavioural disturbance.

The modelling methodology considered source directivity and range-dependent environmental properties. Estimated underwater acoustic levels are presented as sound pressure levels (SPL, L_p), zero-to-peak pressure levels (PK, L_{pk}), and either single-impulse (i.e., per-strike) or accumulated sound exposure levels (SEL, L_E) as appropriate for different noise effect criteria for either continuous (vessels) or impulsive (piling and VSP) noise sources.

1.1. Activity Description

The Dorado Development, located in offshore waters approximately 90 m deep, will include the following noise generating:

- The installation of a single subsea WHP requiring four driven jacket piles for anchoring the platform risers to the seafloor
- The installation of a single subsea FPSO mooring requiring ten piles to tether and anchor the FPSO to the seafloor.
- Vertical Seismic Profiling (VSP) from a crane suspended source during drilling operations.
- FPSO operation under normal operating conditions.
- FPSO offtake operations, including the FPSO under dynamic positioning (DP), an Offshore Support Vessel (OSV) assisting the offtake and a noiseless condensate tanker.

An overview of the modelled area and the modelled vessel configuration for FPSO offtake operations (described in Section 1.2) are shown in Figure 1. A concept layout of the project facilities described above is shown in Figure 2.

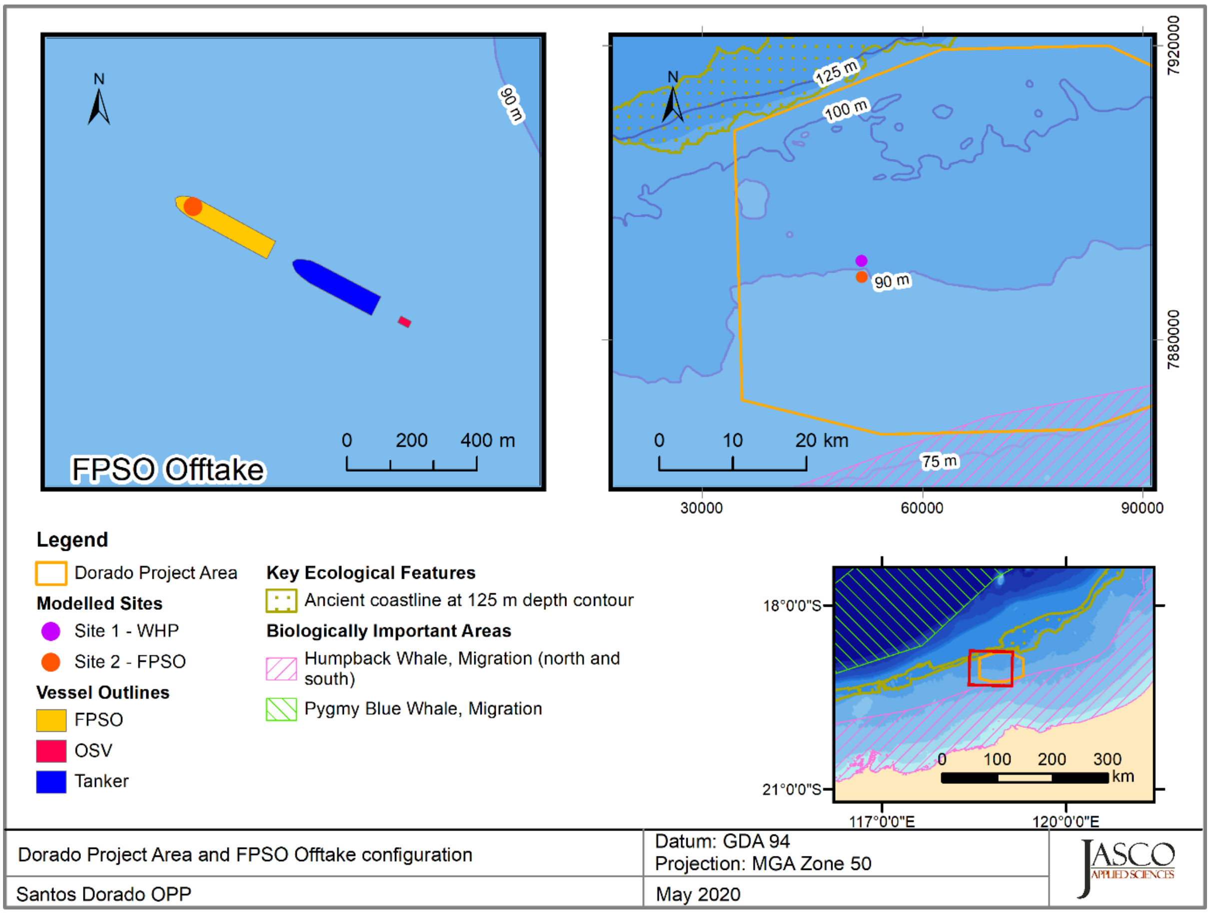

Figure 1. Project overview map and FPSO Offtake configuration used in modelling scenario.

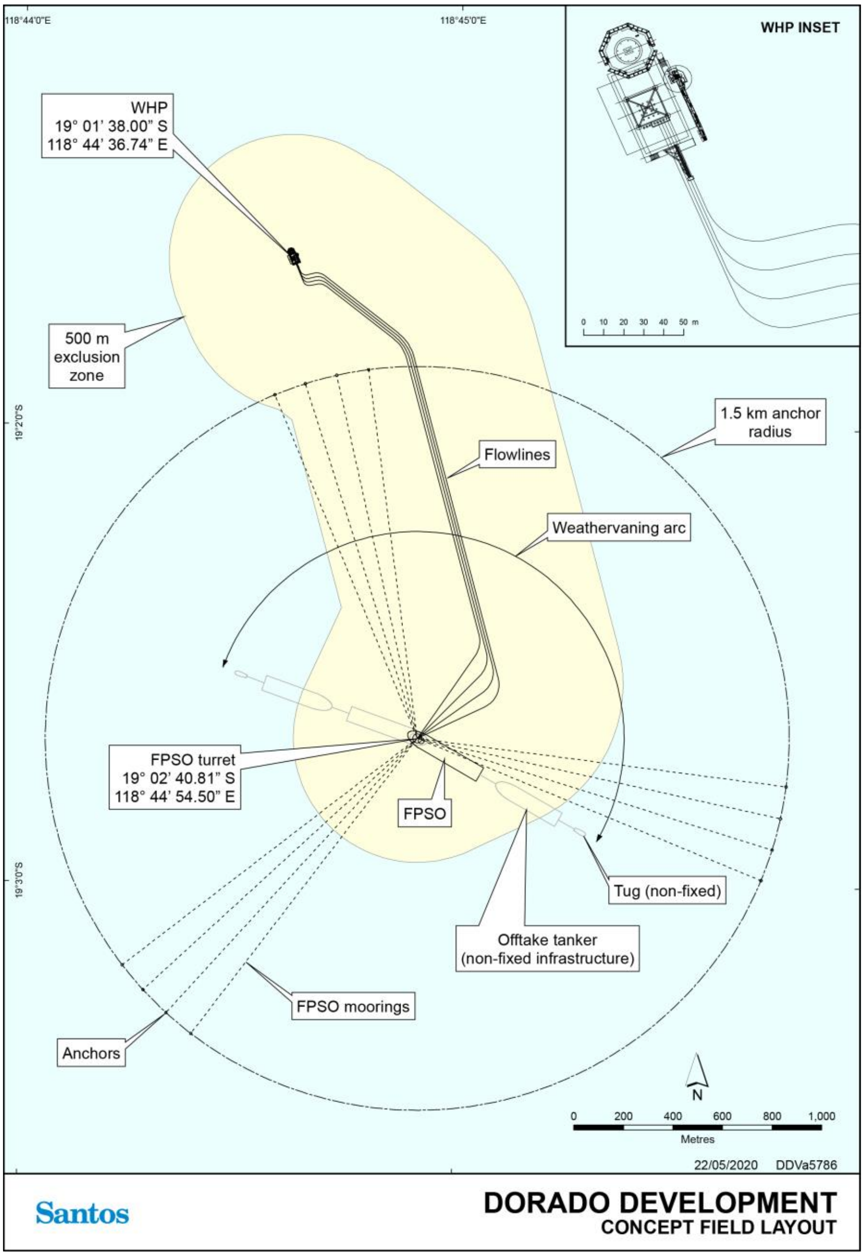

Figure 2. Dorado Development facility layout, the Tug vessel is referred to as an OSV in this report.

1.2. Acoustic Modelling Scenario Details

From the description of the project above, the following representative scenarios have been considered in the underwater noise study to inform the impact assessment. The specific scenarios considered are:

- The installation of a single subsea WHP jacket pile (representative of all four piles).
- The installation of a single subsea FPSO mooring pile (representative of all ten piles).
- Vertical Seismic Profiling (VSP) from a crane suspended source during drilling operations.
- FPSO operational noise for an FPSO under normal operating conditions.
- An Offshore Support Vessel (OSV) supporting offtake operations
- FPSO operational noise during offtake, represented by:
    - The FPSO under dynamic positioning (DP).

- The FPSO under DP, with a noiseless condensate tanker, and the OSV supporting the offtake.

The geographic coordinates for the modelled sites are provided in Table 6. An overview of the modelled area and the modelled vessel configuration for FPSO offtake operations are shown in Figure 1. Site 1 represents the centre of the WHP (and is also used for the VSP) and Site 2 the centre of the turret mooring system on the FPSO.

Table 6. Location details for the modelled sites.

Site	Location Description	Latitude (S)	Longitude (E)	MGA (GDA94), Zone 50		Water depth (m)
				X (m)	*Y* (m)	
1	WHP	19° 01' 38.0010"	118° 44' 36.7440"	683500	7895250	91
2	FPSO	19° 02' 49.5460"	118° 44' 36.7440"	683478	7893050	89

The operations considered in this study will occur at the WHP and FPSO, at depths of approximately 90 m (Table 6). Because activities could take place at any time in the year, a conservative water column sound speed profile (i.e., the profile leading to the longest acoustic propagation) was selected for modelling (July, Appendix F.3.2). The seabed vicinity of the modelled sites consists of a layer of unconsolidated fine sandy sediment underlain by a package of carbonate rock with various degrees of lithification, but likely increasing in cementation/lithification with depth.

JASCO modelled the MHU 600T impact hammer with for use with driving two different pile diameters and wall thicknesses. The MHU 600T subsea impact hammer was considered for driven piles at both sites. The general specifications used for modelling underwater noise from impact piling are provided below in Table 7, detailed scenario specific model input parameters and associated methodology are provided Section 3.1. Only one pile of any type will be driven during a single day.

Table 7. Pile specifications for driven cylindrical steel piles.

Site	Location description	Dimension			Final penetration depth (m)
		Length (m)	Diameter (m)	Wall thickness (mm)	
1	WHP	50	3.0	55	21.5
2	FPSO	40	2.5	100	40.0

2. Noise Effect Criteria

To assess the potential impacts of a sound-producing activity, it is necessary to first establish exposure criteria (thresholds) for which sound levels may be expected to have a negative impact on animals. Whether acoustic exposure levels might injure or disturb marine fauna is an active research topic. Since 2007, several expert groups have developed SEL-based assessment approaches for evaluating auditory injury, with key works including Southall et al. (2007), Finneran and Jenkins (2012), Popper et al. (2014), United States National Marine Fisheries Service (NMFS 2018) and Southall et al. (2019). The number of studies that investigate the level of behavioural disturbance to marine fauna by anthropogenic sound has also increased substantially.

Several sound level metrics, such as PK, SPL, and SEL, are commonly used to evaluate noise and its effects on marine life (Appendix A). In this report, the duration of the SEL accumulation is defined differently depending on the source considered, as per the following:

- For piling: As either a “per-strike” value (i.e., integrated over the time of a single strike), or over all strikes that occur over the driving of a single pile, one pile per 24 h period.
- For VSP: As either a “per-pulse” value (i.e., integrated over the time of a single pulse), or over all impulses that occur in a 24 h period.
- For vessels: Integrated over a 24 h period.

Appropriate subscripts indicate any applied frequency weighting applied (Appendix A.3). The acoustic metrics in this report reflect the updated ANSI and ISO standards for acoustic terminology, ANSI S1.1 (R2013) and ISO 18405:2017 (2017).

This study applies the following noise criteria (Sections 2.1–2.2 and Appendix A.2), chosen for their acceptance by regulatory agencies and because they represent current best available science:

1. Peak pressure levels (PK; L_{pk}) and frequency-weighted accumulated sound exposure levels (SEL; $L_{E,24h}$) from Southall et al. (2019) for the onset of permanent threshold shift (PTS) and temporary threshold shift (TTS) in marine mammals (low-frequency (LF), high-frequency (HF), and very-high-frequency (VHF) cetaceans).
2. Marine mammal behavioural threshold based on the current U.S. National Oceanic and Atmospheric Administration (NOAA 2019) criterion for marine mammals of 160 dB re 1 µPa and 120 dB re 1 µPa (SPL; L_{p}) for impulsive and non-impulsive sound sources, respectively.
3. Sound exposure guidelines for fish, fish eggs, and larvae (Popper et al. 2014).
4. Peak pressure levels (PK; L_{pk}) and frequency-weighted accumulated sound exposure levels (SEL; $L_{E,24h}$) from Finneran et al. (2017) for the onset of permanent threshold shift (PTS) and temporary threshold shift (TTS) in sea turtles.
5. Turtle behavioural response threshold of 166 dB re 1 µPa (SPL; L_{p}) (NSF 2011), as applied by the US National Marine Fisheries Service (NMFS), along with a sound level associated with behavioural disturbance 175 dB re 1 µPa (SPL; L_{p}) (McCauley et al. 2000b, 2000a).
6. Additionally, for comparison to published literature, for VSP only, a no effect sound level for sponges and corals of 226 dB re 1 µPa (PK; L_{pk}), is reported for comparing to Heyward et al. (2018).

A detailed description of the criteria and the background literature is provided in Lucke and McPherson (2020).

2.1. Marine Mammals

There are two categories of auditory threshold shifts or hearing loss: permanent threshold shift (PTS), a physical injury to an animal’s hearing organs; and Temporary Threshold Shift (TTS), a temporary reduction in an animal’s hearing sensitivity as the result of receptor hair cells in the cochlea becoming fatigued.

To help assess the potential for the possible injury and hearing sensitivity changes in marine mammals, this report applies the criteria recommended by Southall et al. (2019), considering both

PTS and TTS. These criteria, along with the applied behavioural criteria (NOAA 2019), are summarised in Tables 8 and 9, with descriptions included in Appendix A.2.1 (auditory impairment) and Appendix A.2.2 (behavioural response), with frequency weighting explained in Appendix A.2.

Table 8. Acoustic effects of impulsive noise on marine mammals: Unweighted SPL, SEL_{24h}, and PK thresholds

Hearing group	NOAA (2019)	Southall et al. (2019)			
	Behaviour	PTS onset thresholds* (received level)		TTS onset thresholds* (received level)	
	SPL (L_p; dB re 1 µPa)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	PK (L_{pk}; dB re 1 µPa)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	PK (L_{pk}; dB re 1 µPa)
Low-frequency cetaceans	160	183	219	168	213
High-frequency cetaceans		185	230	170	224
Very-high-frequency cetaceans		155	202	140	196

* Dual metric acoustic thresholds for impulsive sounds: Use whichever results in the largest isopleth for calculating PTS onset. If a non-impulsive sound has the potential of exceeding the peak sound pressure level thresholds associated with impulsive sounds, these thresholds should also be considered.
L_p denotes sound pressure level period.
$L_{pk,flat}$ denotes peak sound pressure is flat weighted or unweighted.
L_E denotes cumulative sound exposure over a 24 h period.

Table 9. Acoustic effects of continuous noise on marine mammals: Unweighted SPL and SEL_{24h} thresholds.

Hearing group	NOAA (2019)	Southall et al. (2019)	
	Behaviour	PTS onset thresholds (received level)	TTS onset thresholds (received level)
	SPL (L_p; dB re 1 µPa)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)
Low-frequency cetaceans	120	199	179
High-frequency cetaceans		198	178
Very-high-frequency cetaceans		173	153

L_p denotes sound pressure level period and has a reference value of 1 µPa.
L_E denotes cumulative sound exposure over a 24 h period and has a reference value of 1 µPa²s.

2.2. Fish, Sea turtles, Fish Eggs, and Fish Larvae

In 2006, the Working Group on the Effects of Sound on Fish and Sea Turtles was formed to continue developing noise exposure criteria for fish and sea turtles, work begun by a NOAA panel two years earlier. The Working Group developed guidelines with specific thresholds for different levels of effects for several species groups (Popper et al. 2014). The guidelines define quantitative thresholds for three types of immediate effects:

- Mortality, including injury leading to death,
- Recoverable injury, including injuries unlikely to result in mortality, such as hair cell damage and minor haematoma, and
- TTS.

Masking and behavioural effects can be assessed qualitatively, by assessing relative risk rather than by specific sound level thresholds. However, as these depend upon activity-based subjective ranges, these effects are not addressed in this report and are included in Tables 10 and 12 for completeness only. Because the presence or absence of a swim bladder has a role in hearing, fish's susceptibility to injury from noise exposure depends on the species and the presence and possible role of a swim bladder in hearing. Thus, different thresholds were proposed for fish without a swim bladder (also appropriate for sharks and applied to whale sharks in the absence of other information), fish with a swim bladder not used for hearing, and fish that use their swim bladders for hearing. Sea turtles, fish eggs, and fish larvae are considered separately.

2.2.1. Impulsive noise

Impulsive noise from both piling and airguns (VSP) is assessed in this study, the relevant effects thresholds from Popper et al. (2014) are listed in Table 10. In general, whether an impulsive sound adversely effects fish behaviour depends on the species, the state of the individual exposed, and other factors.

The SEL metric integrates noise intensity over some period of exposure. Because the period of integration for regulatory assessments is not well defined for sounds that do not have a clear start or end time, or for very long-lasting exposures, an exposure evaluation time must be defined. Southall et al. (2007) defines the exposure evaluation time as the greater of 24 h or the duration of the activity. Popper et al. (2014) recommend a standard period of the duration of the activity; however, the publication also includes caveats about considering the actual exposure times if fish move. Integration times in this study for piling have been applied over the time a single pile was driven since only one pile is expected to be driven per day, while for VSP operations it is over the total number of impulses per day.

Table 10. Criteria for pile driving and seismic noise exposure for fish, adapted from Popper et al. (2014).

Type of animal	Mortality and Potential mortal injury	Impairment			Behaviour
		Recoverable injury	TTS	Masking	
Fish: No swim bladder (particle motion detection)	> 219 dB SEL_{24h} or > 213 dB PK	> 216 dB SEL_{24h} or > 213 dB PK	>> 186 dB SEL_{24h}	Pile driving: (N) Moderate (I, F) Low Seismic: (N, I, F) Low	(N) High (I) Moderate (F) Low
Fish: Swim bladder not involved in hearing (particle motion detection)	210 dB SEL_{24h} or > 207 dB PK	203 dB SEL_{24h} or > 207 dB PK	>> 186 dB SEL_{24h}	Pile driving: (N) Moderate (I, F) Low Seismic: (N, I, F) Low	(N) High (I) Moderate (F) Low
Fish: Swim bladder involved in hearing (primarily pressure detection)	207 dB SEL_{24h} or > 207 dB PK	203 dB SEL_{24h} or > 207 dB PK	186 dB SEL_{24h}	Pile driving: (N, I) High (F) Moderate Seismic: (N, I) Low (F) Moderate	(N, I) High (F) Moderate
Fish eggs and fish larvae	> 210 dB SEL_{24h} or > 207 dB PK	(N) Moderate (I) Low (F) Low	(N) Moderate (I) Low (F) Low	Pile driving: (N) Moderate (I, F) Low Seismic: (N, I, F) Low	(N) Moderate (I, F) Low

Peak sound pressure level dB re 1 µPa; SEL_{24h} dB re 1µPa^2·s.
All criteria are presented as sound pressure even for fish without swim bladders since no data for particle motion exist.
Relative risk (high, moderate, low) is given for animals at three distances from the source defined in relative terms as near (N), intermediate (I), and far (F).

2.2.1.1. Sea turtles

There is a paucity of data regarding responses of sea turtles to acoustic exposure, and no studies of hearing loss due to exposure to loud sounds. McCauley et al. (2000b) observed the behavioural response of caged sea turtles–green (*Chelonia mydas*) and loggerhead (*Caretta caretta*)–to an approaching seismic airgun. For received levels above 166 dB re 1 µPa (SPL), the sea turtles increased their swimming activity and above 175 dB re 1 µPa they began to behave erratically, which was interpreted as an agitated state. The 166 dB re 1 µPa level has been used as the threshold level for a behavioural disturbance response by NMFS and applied in the Arctic Programmatic Environment Impact Statement (PEIS) (NSF 2011). At that time, and in the absence of any data from which to determine the sound levels that could injure an animal, TTS or PTS onset were considered possible at an SPL of 180 dB re 1 µPa (NSF 2011). Some additional data suggest that behavioural responses occur closer to an SPL of 175 dB re 1 µPa, and TTS or PTS at even higher levels (Moein et al. 1995), but the received levels were unknown and the NSF (2011) PEIS maintained the earlier NMFS criteria levels of 180 and 166 dB re 1 µPa (SPL) for injury and behavioural response, respectively. Popper et al. (2014) suggested injury to sea turtles could occur for sound exposures above 207 dB re 1 µPa (PK) or above 210 dB re 1 µPa^2·s (SEL_{24h}). Sound levels defined by Popper et al. (2014) show that animals are very likely to exhibit a behavioural response when they are near an airgun (tens of metres), a moderate response if they encounter the source at intermediate ranges (hundreds of metres), and a low response if they are far (thousands of meters) from the airgun.

Finneran et al. (2017) presented revised thresholds for turtle injury (PTS) and TTS, considering both PK and frequency weighted SEL, which have been applied in this study, along with the NMFS criterion for behavioural response (SPL of 166 dB re 1 µPa), and a criterion for behavioural disturbance (SPL of 175 dB re 1 µPa) (Moein et al. 1995, McCauley et al. 2000b, 2000a) (Table 11).

Table 11. Acoustic effects of impulsive noise on sea turtles: Unweighted SPL, SEL_{24h}**,** and PK thresholds

NSF (2011)	**Moein et al. (1995), McCauley et al. (2000b), (2000a)**	**Finneran et al. (2017)**			
Behaviour		**PTS onset thresholds* (received level)**		**TTS onset thresholds* (received level)**	
SPL (L_p; dB re 1 µPa)		Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa^2·s)	PK (L_{pk}; dB re 1 µPa)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa^2·s)	PK (L_{pk}; dB re 1 µPa)
166	175	204	232	189	226

* Dual metric acoustic thresholds for impulsive sounds: Use whichever results in the largest isopleth for calculating PTS onset. If a non-impulsive sound has the potential of exceeding the peak sound pressure level thresholds associated with impulsive sounds, these thresholds should also be considered.
L_p denotes sound pressure level period and has a reference value of 1 µPa.
$L_{pk,flat}$ denotes peak sound pressure is flat weighted or unweighted and has a reference value of 1 µPa.
L_E denotes cumulative sound exposure over a 24 h period and has a reference value of 1 µPa^{2}s.

2.2.2. Continuous noise

Table 12 lists the relevant effects thresholds from Popper et al. (2014) for shipping and continuous noise. Some evidence suggests that fish sensitive to acoustic pressure show a recoverable loss in hearing sensitivity, or injury when exposed to high levels of noise (Scholik and Yan 2002, Amoser and Ladich 2003, Smith et al. 2006); this is reflected in the SPL thresholds for fish with a swim bladder involved in hearing.

Finneran et al. (2017) presented revised thresholds for turtle injury, considering frequency weighted SEL, which have been applied in this study for vessels (Table 13).

Table 12. Criteria for vessel (continuous) noise exposure for fish, adapted from Popper et al. (2014)

Type of animal	Mortality and Potential mortal injury	Impairment			Behaviour
		Recoverable injury	TTS	Masking	
Fish: No swim bladder (particle motion detection)	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) Moderate (I) Low (F) Low	(N) High (I) High (F) Moderate	(N) Moderate (I) Moderate (F) Low
Fish: Swim bladder not involved in hearing (particle motion detection)	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) Moderate (I) Low (F) Low	(N) High (I) High (F) Moderate	(N) Moderate (I) Moderate (F) Low
Fish: Swim bladder involved in hearing (primarily pressure detection)	(N) Low (I) Low (F) Low	170 dB SPL for 48 h	158 dB SPL for 12 h	(N) High (I) High (F) High	(N) High (I) Moderate (F) Low
Sea turtles	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) Moderate (I) Low (F) Low	(N) High (I) High (F) Moderate	(N) High (I) Moderate (F) Low
Fish eggs and fish larvae	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) High (I) Moderate (F) Low	(N) Moderate (I) Moderate (F) Low

Sound pressure level dB re 1 µPa.
Relative risk (high, moderate, low) is given for animals at three distances from the source defined in relative terms as near (N), intermediate (I), and far (F).

Table 13. Acoustic effects of continuous noise on sea turtles, weighted SEL_{24h}, Finneran et al. (2017).

PTS onset thresholds (received level)	TTS onset thresholds (received level)
220	200

3. Methods

This section describes the methods used to characterise acoustic sources (driven piles, vessel noise and VSP), as well as the acoustic propagation models and frequency ranges considered for estimation of acoustic fields.

3.1. Pile driving

To predict the acoustic field around the pile driving, JASCO's Pile Driving Source Model (PDSM; Appendix B) was used in conjunction with JASCO's Full Waveform Range-dependent Acoustic Model (FWRAM, Appendix E.2) at frequencies from 10 Hz to 1 kHz. In addition, an empirical extrapolation was applied to these results to extend the frequency range up to 25 kHz.

The 24 hour SEL results were determined through the accumulation of energy across the entire pile driving operation, accounting for the per-strike sound fields modelled for three phases representing different seafloor penetration depths.

3.1.1. Per-strike Modelling

For impact pile driving sounds, time-domain representations of the pressure waves generated in the water are required for calculating sound pressure level (SPL), sound exposure level (SEL), and peak sound pressure level (PK). Appendix A.1 describes these sound level metrics. The following steps describe the general approach applied in this study to model sounds from impact pile driving activities:

1. The theory of underwater sound propagation is applied to predict how sound propagates from the pile into the water column as a function of range, depth, and azimuthal direction. Propagation depends on several conditions including the frequency content of the sound, the bathymetry, the sound speed in the water column, and seabed geoacoustics (Appendix F.3 describes environmental properties such as bathymetry, sound speed profile, and geoacoustics).
2. Piles driven into the seabed by impact piling are characterised as vertically distributed sound-radiating sources. This characterisation strongly depends on the rate and extent of pile penetration, pile dimensions, and pile driving equipment.
3. The propagated sound field is used to compute received levels over a grid of simulated receivers from which distances to criteria thresholds and maps of ensonified areas are generated.

To model sounds resulting from impact pile driving of cylindrical pipes, PDSM (Appendix B), a physical model of pile vibration and near-field sound radiation (MacGillivray 2014), is used in conjunction with the GRLWEAP 2010 wave equation model (GRLWEAP, Pile Dynamics 2010). Figure 3 shows the time history of the hammer force at the top of the pile that is predicted by GRLWEAP.

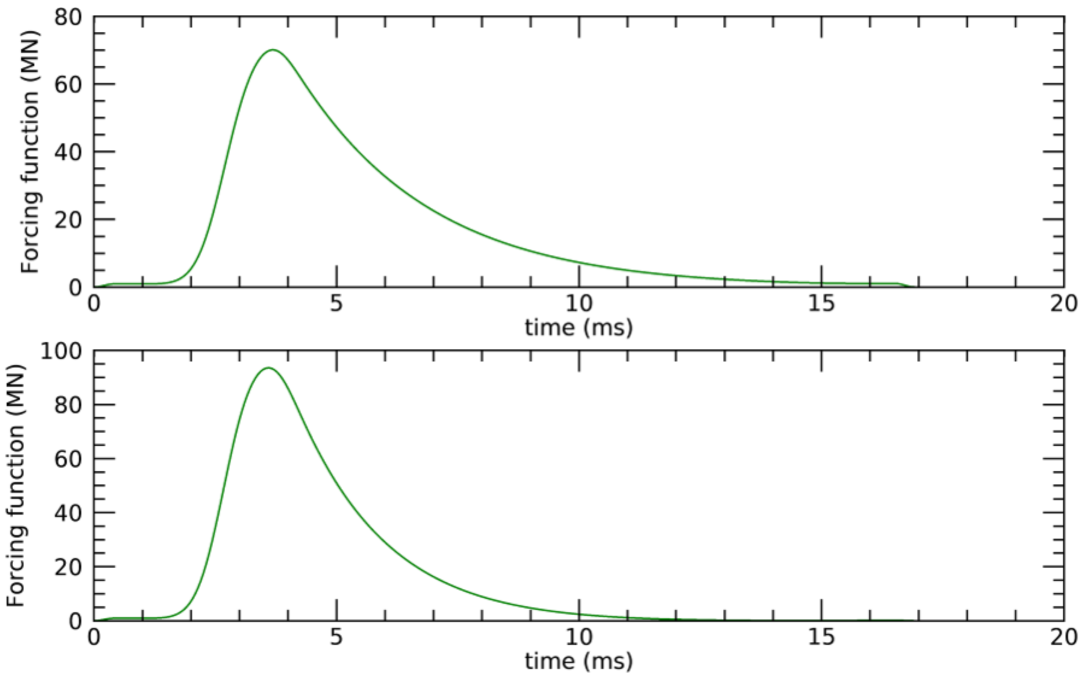

Figure 3. Force (in meganewtons) at the top of the pile corresponding to impact pile driving using the MHU 600T impact hammer for the WHP jacket pile (top) and FPSO anchor pile (bottom), computed using the GRLWEAP 2010 wave equation model for the WHP jacket pile and FPSO anchor pile.

The forcing functions (Figure 3) are used by the PDSM to obtain equivalent pile driving signatures for a vertical array of discrete point sources (Appendix B). These represent the pile as an acoustic source and account for parameters (pile type, material, size, and length), the pile driving equipment, and approximate pile penetration rate. The amplitude and phase of the point sources along the pile are computed so they collectively mimic the time-frequency characteristics of the acoustic wave at the pile wall that results from a hammer strike at the top of the pile. This approach accurately estimates spectral levels within the band 10–1000 Hz where most of the energy from impact pile driving is concentrated.

Time-domain Full Waveform Range-dependent model (FWRAM; Appendix E.2) calculates sound propagation from physically distributed impulsive sources and is valid at all distances. In the present study, received sound levels were calculated using FWRAM along transects at 180 azimuths out to 80 km from the source.

Source band levels at 1000 Hz were extrapolated up to 25 kHz using a 20 dB/decade decay rate to match acoustic measurements of impact pile driving of similarly-sized piles (Illingworth & Rodkin 2007, Matuschek and Betke 2009).

Receiver depths are chosen to span the entire water column over the modelled area, from 2 to 230 m, with a 2 m depth increment. To produce maps of received sound level distributions and to calculate distances to specified sound level thresholds, the maximum-over-depth level is calculated at each modelled easting and northing position within the considered region. The radial grids of maximum-over-depth levels are then resampled (by linear triangulation) to produce a regular Cartesian grid with a cell size of 20 m. The contours and threshold ranges were calculated from these flat Cartesian projections of the modelled acoustic fields (Appendix F.1).

3.1.2. Accumulated SEL Modelling for Pile Driving

The modelling approach outlined in Sections 3.1.1 provides per-strike SEL for three stages of pile driving (i.e., three penetration depths). Because a single pile will be driven per day and the piling noise level far exceeds any background, the corresponding sound exposure level can be denoted as SEL_{24h} even though the effective period of accumulation is the estimated time for fully driving a single pile. The accumulated SEL over a single pile, or the SEL_{24h}, depends on the total number of strikes

Total driving time was estimated assuming continuous piling at a rate of approximately 0.50 strikes/second (30 strikes/minute) for the MHU 600T hammer. The number of strikes required for the driving of the pile were determined based upon a drivability profile estimated in consultation with Santos. The SEL_{24h} was computed by adjusting the single-strike SEL by $10*\log_{10}(N)$, where the total number of strikes. A summary of the total number of strikes per penetration depth and over the entire pile is provided in Table 14.

Table 14. Total number of strikes and driving time. Strikes were broken down into stages corresponding to the three modelled penetrations for the MHU 600T hammer.

Pile Type	Hammer	Modelled penetration (m)	Penetration range for accumulated SEL (m)	Number of strikes	Average Penetration rate (mm/strike)	Total number of strikes	Time for full penetration (hr)
WHP jacket pile	MHU 600T	3.5	1 to 6	500	10	2883	1.6
		11	6 to 16	1333	7.5		
		18.75	16 to 21.25	1050	5		
FPSO anchor pile	MHU 600T	3.5	1 to 6	500	10	8530	4.7
		13.6	6 to 21.25	2480	6.3		
		30.6	21.25 to 40	5550	3.3		

3.2. Vertical Seismic Profiling (VSP)

The pressure signature of the individual airguns and the composite 1/3-octave-band point-source equivalent directional levels (i.e., source levels) of the 750 in^3 VSP source suspended at 5 m were modelled with JASCO's Airgun Array Source Model (AASM; Appendix C.1).

Three sound propagation models were used to predict the acoustic field around the VSP source:

- Combined range-dependent parabolic equation and Gaussian beam acoustic ray-trace model (MONM-BELLHOP, 10 Hz to 25 kHz; Appendix E.3).
- FWRAM (5 Hz to 1024 Hz; Appendix E.2).
- Wavenumber integration model (VSTACK, 10 Hz to 2048 Hz; Appendix E.4).

The models were combined to characterise the acoustic fields at short and long ranges in terms of SEL, SPL, PK, and PK-PK. Appendix E details each model. MONM was used to calculate SEL of a 360° area around the source location. VSTACK was used to calculate PK and PK-PK transects at the seafloor at close range from the seismic source. FWRAM was used to calculate PK and PK-PK in the entire water column along four selected transects, and to obtain a range dependent conversion factor to estimate SPL from the MONM-BELLHOP SEL results.

3.2.1. Acoustic Source Model

AASM accounts for the notional pressure signatures of each source element with respect to the effects of surface-reflected signals on bubble oscillations and inter-bubble interactions, the surface-reflected signal (known as surface ghost) is not included in the far-field source signatures. The acoustic propagation models account for those surface reflections, which are a property of the propagating medium rather than the source.

AASM considers:

- Array layout.
- Volume, depth, and firing pressure of each airgun.
- Interactions between different airguns in the array.

The VSP source considered was modelled over AASM's full frequency range, up to 25 kHz; Appendix C.1 details this model.

3.2.2. Per-pulse Modelling

To assess sound levels with MONM-BELLHOP, the sound field modelling calculated propagation losses up to distances at least 80 km from the source, with a horizontal separation of 20 m between receiver points along the modelled radials. The sound fields were modelled with a horizontal angular resolution of $\Delta\theta$ = 2.5° for a total of N = 144 radial planes. Receiver depths were chosen to span the entire water column over the modelled areas, from 2 m to a maximum of 230 m, with step sizes that increased with depth. To supplement the MONM results, high-frequency results for propagation loss were modelled using Bellhop for frequencies from 2 to 25 kHz. The MONM and Bellhop results were combined to produce results for the full frequency range of interest.

FWRAM was run to 80 km along only four radials for computational efficiency from 5 to 1024 Hz in 1 Hz steps. In the context of VSP source geometry (see Appendix C.2) the radials were modelled perpendicular to the sagittal plane of the array and parallel to the sagittal plane of the array. This was done to compute SEL-to-SPL conversions (Appendix F.2) but also to quantify water column PK and PK-PK. The horizontal range step was dependent on frequency and ranged from 50 m at lower frequencies to 10 m above 800 Hz.

The maximum modelled range for VSTACK was 1000 m and a variable receiver range increment that increased away from the source, from 10 to 25 m, was used. Received levels were computed at the seafloor.

3.2.3. Multiple-pulse Modelling

The VSP operation was assessed in this report by considering several potential scenarios for a maximum number of pulses per 24 h. The SEL was assessed over 24 h by adjusting the single-pulse SEL by $10*\log_{10}(N)$, where the total number of pulses N was 5, 10, 15, 25, 50, 100, 150, 200, and 250,and 300 per 24 h at the Dorado WHP location (Site 1).

3.3. Vessel noise (FPSO and OSV)

JASCO's Marine Operations Noise Model (MONM-BELLHOP Appendix E.3) was used to predict the acoustic field at frequencies of 10 Hz to 63 kHz for all vessels.

For all vessels, the sound pressure level (SPL) modelling results were converted to SEL by the duration of the measurement, which is appropriate for a continuous noise source. As SEL was assessed over 24 h, the conversion from SPL was obtained by increasing the levels by $10*\log_{10}(T)$, where T is 86,400 (the number of seconds in 24 h).

The acoustic source parameters for the FPSO are detailed in Section 3.3.1 and those for the OSV in Section 3.3.2.

3.3.1. Floating Production, Storage, and Offloading (FPSO) facility

The proposed FPSO facility is a dynamically positioned production vessel approximately 370 m long and 67 m wide with a draft of 16 m. While in DP mode, it operates on one stern thruster positioned laterally on the keel at the stern of the ship. The vessel type and specifications are similar to production vessels *Ngujima Yin* and *Nganhurra*, from which JASCO gathered measurements in 2010 (Erbe et al. 2013). The measured spectra for these two vessels were averaged and used as a surrogate for the FPSO facility. Because the *Ngujima Yin* and *Nganhurra* were moored, they were not offloading, and the weather was calm, they were not under DP when they were measured. These averaged source levels were used in this report to model FPSO operations without DP.

To model operations that include DP, sound levels of thruster noise were added to the (non-DP) source spectrum. Sound levels for DP thruster noise were based on measurements of the dive support vessel *DSV Fu Lai* (MacGillivray 2006). The composite source spectrum (i.e., non-DP and DP components) was adjusted for the difference in total operational power level between the DSV *Fu Lai* and the FPSO facility using the following equation:

$$SL = SL_{FuLai} + 10\log(HP/HP_{ref}) \,, \quad (1)$$

where HP_{ref} is the level of reference power. The source spectrum was additionally modified to consider the operational level of the *Fu Lai* thrusters relative to the desired operational level for the FPSO facility. Given that DP does not require full thrust, the *Fu Lai*'s thrusters only operated at between 20% and 30% of capacity when measured. To achieve a conservative estimate, the FPSO facility thruster was modelled at 50% power capacity. In addition to the adjustment in Eq.1, an offset of $10*\log_{10}(5/2.94)$ was applied to the composite source spectrum, to account for the difference in thruster power between the *Ngujima Yin* and *Nganhurra*, and the FPSO considered in this study.

The acoustic modelling source depth was determined by assuming the bottoms of the thruster was at the draft of the vessel, but the noise from cavitation is known (Wright and Cybulski 1983) to be centralised at approximately three quarters of the propeller's height.

In the absence of information about the propeller diameter and vertical position, modelling was conducted assuming point sources at 16 m to be conservative. For modelling, it was assumed that the thruster operated at the middle (50%) of their constant power range, at a constant speed. The thrusters are located at the stern section of the vessel; for modelling purposes, however, the source location was placed in the planar centre of the vessel to approximate a point source. Because this assessment is focused on the far-field noise from all sources on the vessel (including not just thruster noise, but also noise from ancillary equipment for power generation, etc.) the point source approximation is suitable. Figure 4 shows 1/3-octave-band source levels and the legend in Figure 4 indicates the overall broadband source level for the FPSO facility (with and without DP).

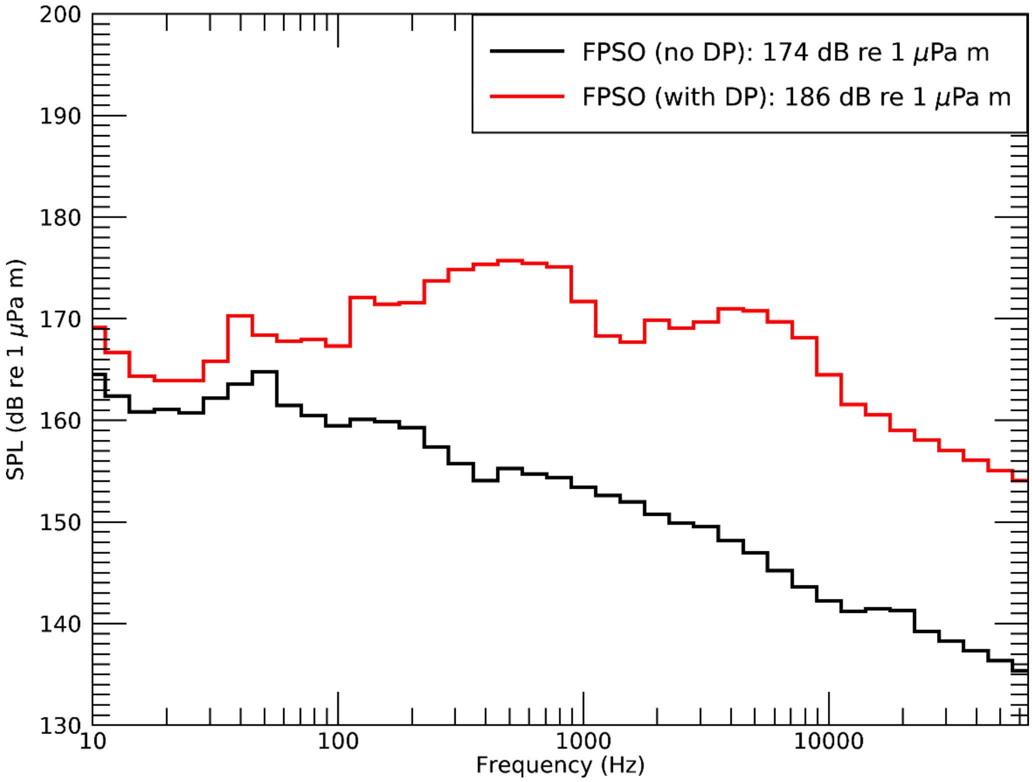

Figure 4. *FPSO*: 1/3-octave-bands of modelled FPSO facility without and with dynamic positioning (DP).

3.3.2. Offshore Support Vessel (OSV)

The estimates of acoustic source levels and sound spectrum for the support vessel were based on the *MMA Inscription* platform supply vessel, referred to in this report as an Offshore Support Vessel (OSV) (Figure 5). The *MMA Inscription*, of length 87.08 m, breadth of 18.8 m and maximum draft of 5.9 is equipped with two bow (main) azimuthal thrusters, one stern retractable azimuthal thruster, and one bow thruster. Since parameters such as propeller size or thruster vertical position were not available, thrusters were modelled at depth 5.9 m, equal to the draft. The bow thrusters are 2000 kW maximum continuous power input each, while the bow thruster is 910 kW maximum continuous power input. For this modelling, the stern retractable thruster was not included. Figure 6 shows the thruster locations.

Source levels for the *MMA Inscription* were obtained based on those of the Damen platform supply vessel 3300CD (length 80.08 m, breadth of 16.8 m and maximum draft of 6.9), which was used in previous studies (Zykov 2016). For the Damen 3300CD, the bow (main) thrusters are 2000 kW maximum continuous power input each, while smaller bow thrusters are 735 kW maximum continuous power input. Unlike Zykov (2016), in which thrusters were assumed to operate at full capacity, modelling in this study was conducted assuming a 25% capacity. For this reason, thrusters levels from Zykov (2016) were offset by $10*\log_{10}(0.25)$ for the main thrusters, and by $10*\log_{10}(0.25)+10*\log_{10}(910/735)$ for the bow thruster. The source levels for individual thrusters are shown in Figure 7.

Figure 5. Image of the *MMA Inscription* (MMA Offshore 2019).

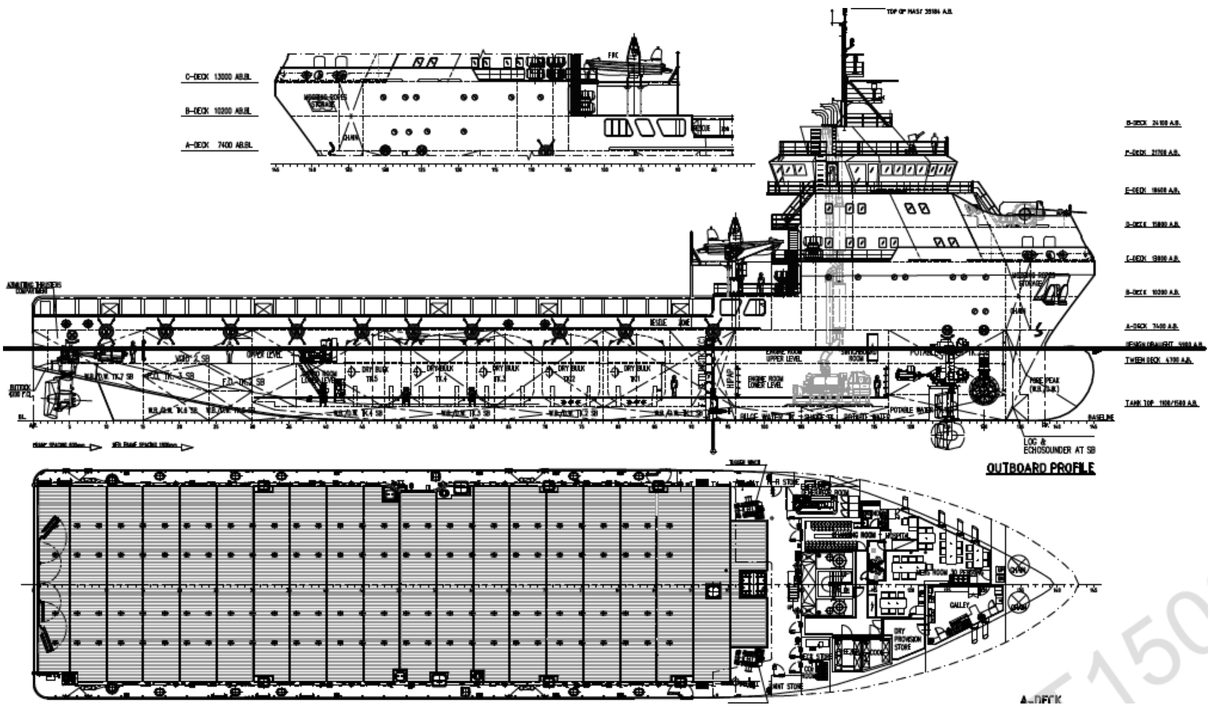

Figure 6. Nominal dimensions and thruster locations (circles) of the *MMA Inscription* (MMA Offshore 2019).

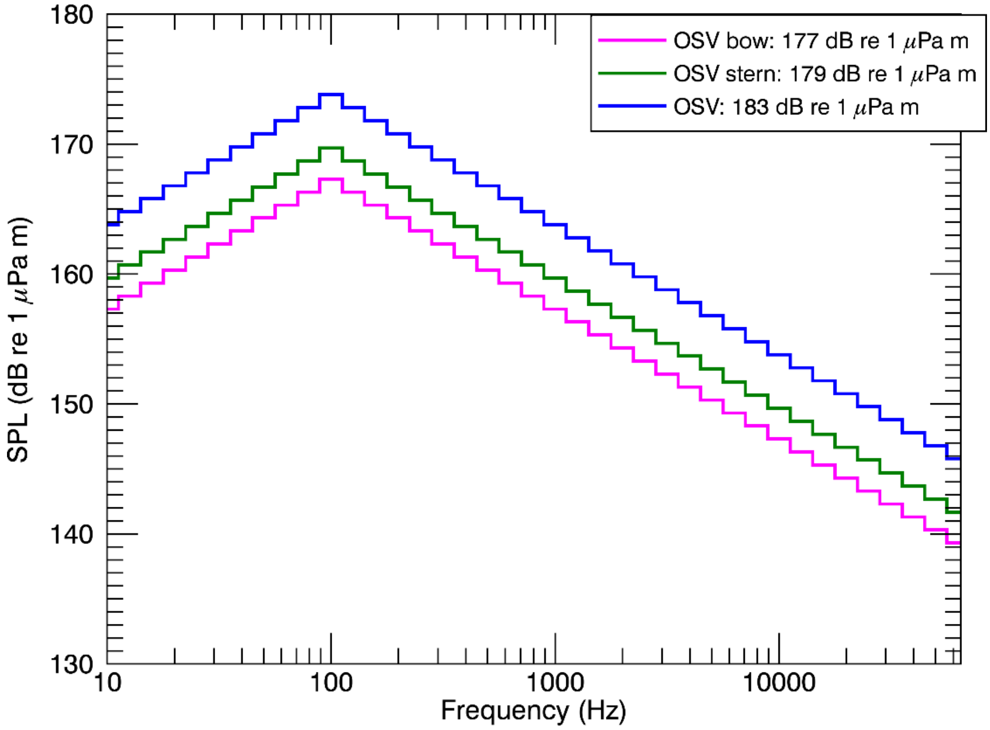

Figure 7. *OSV*: 1/3-octave-band source levels of both individual bow and stern thrusters and composite curve including the two individual stern thrusters and the bow thruster.

4. Results

For the results and tables presented below where a dash is used in place of a horizontal distance, these thresholds may or may not be reached due to the discretely sampled radial increments of the modelled sound fields. A dash therefore is an indication that effect levels for the associated metric may only be reached within a very close proximity to a given source.

4.1. Well Head Platform (WHP) Piling

4.1.1. Received levels at 10 m

Since piles are distributed and directional sources, they cannot be accurately approximated by a point source with corresponding source levels (extended detail is provided in Appendix B). It is possible to compare the maximum modelled levels at short distances from the piles. Figure 8 shows the 1/3-octave-band levels for the receiver with the highest SEL at a horizontal range of 10 m, for the three modelled penetrations. The levels above 1000 Hz were extrapolated using a 20 dB/decade decay rate to match acoustic measurements of impact pile driving of similarly sized piles (Illingworth & Rodkin 2007, Matuschek and Betke 2009). The modelled results at a distance of 10 m are included to provide results comparable to other pile driving reports and literature, such as Illingworth & Rodkin (2007), and Denes et al. (2016).

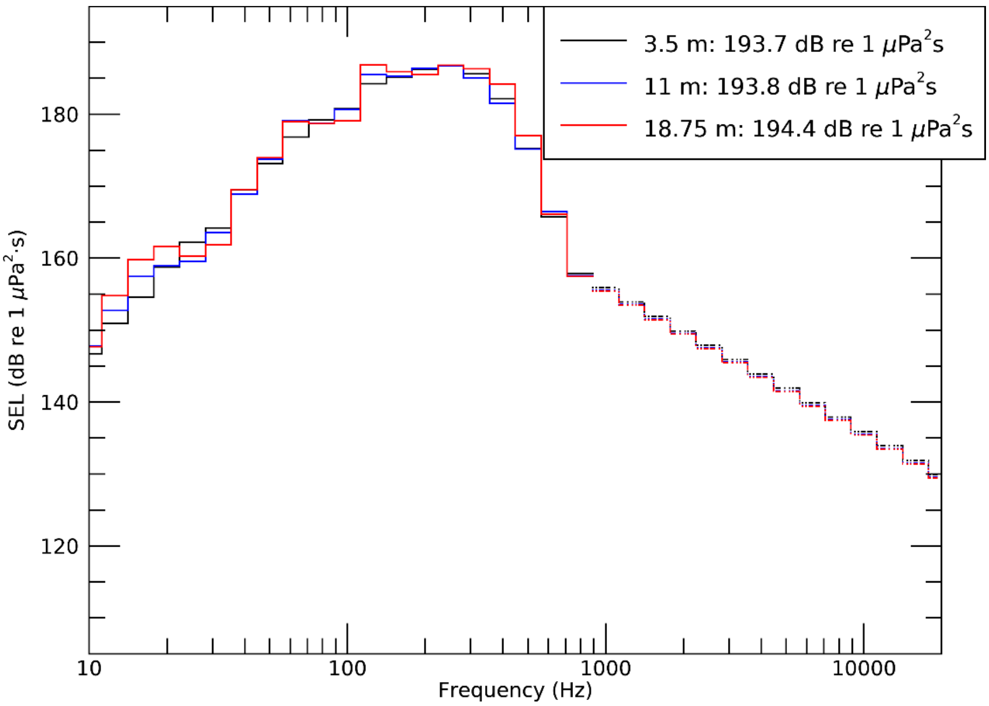

Figure 8. *WHP piling*: 1/3-octave-band levels for the receiver with highest SEL at 10 m horizontal range for impact pile driving using the MHU 600T hammer, after high-frequency extrapolation (dashes indicate extrapolated portion of the spectrum). Legend items indicate the modelled pile penetration and the broadband SEL in dB re 1 µPa²·s.

4.1.2. Per-strike sound fields

Per-strike results for the proposed pile driving are presented in this section for maximum-over-depth SPL, SEL, and PK (tables in Section 4.1.2.1), maps and sound field vertical slices (Section 4.1.2.2).

4.1.2.1. Tabulated results

Tables 15–19 show the estimated distances for the various applicable per-strike effects criteria and isopleths of interest as maximum-over-depth.

Table 15. *WHP piling, per-strike SEL:* Maximum (R_{max}) and 95% ($R_{95\%}$) horizontal distances (in km) from the pile to modelled maximum-over-depth isopleths for the MHU 600T hammer.

Per-strike SEL (L_E; dB re 1 µPa²·s)	Penetration depth					
	3.5 m		11 m		18.75 m	
	R_{max} (km)	$R_{95\%}$ (km)	R_{max} (km)	$R_{95\%}$ (km)	R_{max} (km)	$R_{95\%}$ (km)
190	0.03	0.03	0.06	0.06	0.06	0.06
180	0.35	0.34	0.34	0.33	0.31	0.30
170	0.77	0.73	0.73	0.71	0.70	0.68
160	2.82	2.71	2.73	2.62	2.65	2.54
150	6.46	6.22	6.34	6.12	6.62	6.39
140	18.2	17.0	18.9	17.7	19.9	18.8
130	56.0	50.6	56.5	51.6	57.4	53.2
120	>80.0	/	>80.0	/	>80.0	/

A slash indicates that $R_{95\%}$ radius to threshold is not reported when the R_{max} is greater than the maximum modelling extent.

Table 16. *WHP piling, SPL:* Maximum (R_{max}) and 95% ($R_{95\%}$) horizontal distances (in km) from the pile to modelled maximum-over-depth isopleths for the MHU 600T hammer.

SPL (L_p; dB re 1 µPa)	Penetration depth					
	3.5 m		11 m		18.75 m	
	R_{max} (km)	$R_{95\%}$ (km)	R_{max} (km)	$R_{95\%}$ (km)	R_{max} (km)	$R_{95\%}$ (km)
200	–	–	0.02	0.02	0.05	0.05
190	0.30	0.30	0.30	0.29	0.28	0.27
180	0.63	0.61	0.60	0.58	0.62	0.60
170	2.51	2.41	2.40	2.31	2.33	2.24
160	5.30	5.05	5.24	5.00	5.40	5.20
150	15.2	14.4	16.1	15.2	17.7	16.3
140	49.5	44.8	49.8	45.1	51.0	46.2
130	>80.0	/	>80.0	/	>80.0	/

A dash indicates the threshold is not reached within the limits of the modelling resolution (20 m).
A slash indicates that $R_{95\%}$ radius to threshold is not reported when the R_{max} is greater than the maximum modelling extent.

Table 17. *WHP piling, marine mammal and turtle behavioural response thresholds, SPL*: Maximum (R_{max}) and 95% ($R_{95\%}$) horizontal distances (in km) from the pile to modelled maximum-over-depth isopleths per penetration depth for the MHU 600T hammer.

Threshold	**Penetration depth**					
	3.5 m		**11 m**		**18.75 m**	
	R_{max} (km)	$R_{95\%}$ (km)	R_{max} (km)	$R_{95\%}$ (km)	R_{max} (km)	$R_{95\%}$ (km)
Marine mammal behavioural response (160 dB re 1 µPa SPL) (NOAA 2019)	5.30	5.05	5.24	5.00	5.40	5.20
Turtle behavioural response (166 dB re 1 µPa SPL) (NSF 2011)	3.51	3.36	3.41	3.27	3.33	3.20
Turtle behavioural disturbance (175 dB re 1 µPa SPL) (McCauley et al. 2000b, 2000a)	1.39	1.34	1.32	1.27	1.29	1.23

Table 18. *WHP piling, marine mammal and turtle PTS and TTS PK thresholds*: Maximum (R_{max}) horizontal distances (in m) from the pile to maximum-over-depth isopleths for the MHU 600T hammer.

Hearing group	**PK threshold (L_{pk}; dB re 1 µPa**	**Penetration depth**		
		3.5 m	**11 m**	**18.75 m**
		R_{max} (m)	R_{max} (m)	R_{max} (m)
Low-frequency cetaceans (PTS)	219	20	20	63
Low-frequency cetaceans (TTS)	213	172	156	89

Sea turtles (PTS)	232	–	–	–
Sea turtles (TTS)	226	–	–	–

A dash indicates the threshold is not reached within the limits of the modelling resolution (20 m).

Table 19. *WHP piling, mortality, and potential mortal recoverable injury thresholds (peak pressure level metric) for fish, fish eggs, and fish larvae*: Maximum (R_{max}) horizontal distances (in m) from the pile.

Marine fauna group	**PK threshold (L_{pk}; dB re 1 µPa**	**Penetration depth**		
		3.5 m	**11 m**	**18.75 m**
		R_{max} (m)	R_{max} (m)	R_{max} (m)
Fish: No swim bladder	213	172	156	89
Fish: Swim bladder not involved in hearing; Swim bladder involved in hearing Fish eggs, and larvae	207	420	396	358

4.1.2.2. Sound field maps and vertical slices

Maps of the per-strike SPL results associated with the three modelled penetration depths for driving the WHP jacket pile are shown in Figures 9–11 for the MHU 600T hammer. The isopleths for marine mammal behavioural criteria (160 dB re 1 µPa) for each of the three considered penetration depths are also provided. Vertical slice plots for all penetrations are shown in Figures 12–14. Per-strike SEL maps are shown in Appendix G.1.

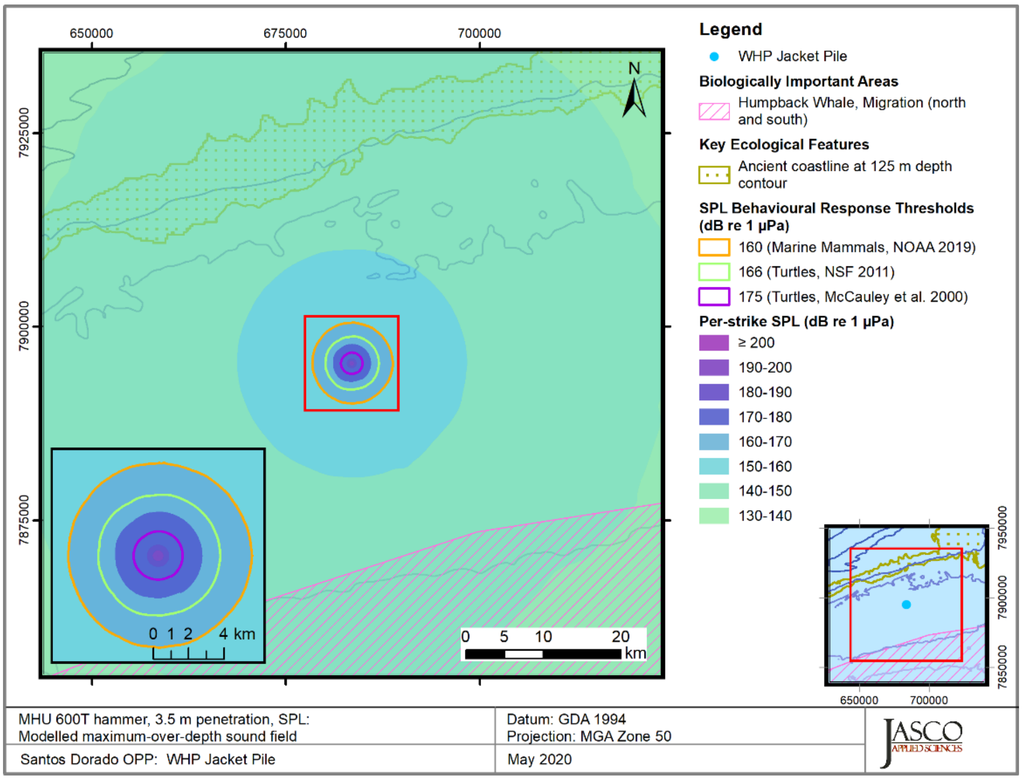

Figure 9. *WHP piling, SPL, 3.5 m penetration depth*: Sound level contour map, showing maximum-over-depth results. Isopleths for sea turtles (166 and 175 dB re 1 µPa) and marine mammal (160 dB re 1 µPa) behavioural criteria are shown.

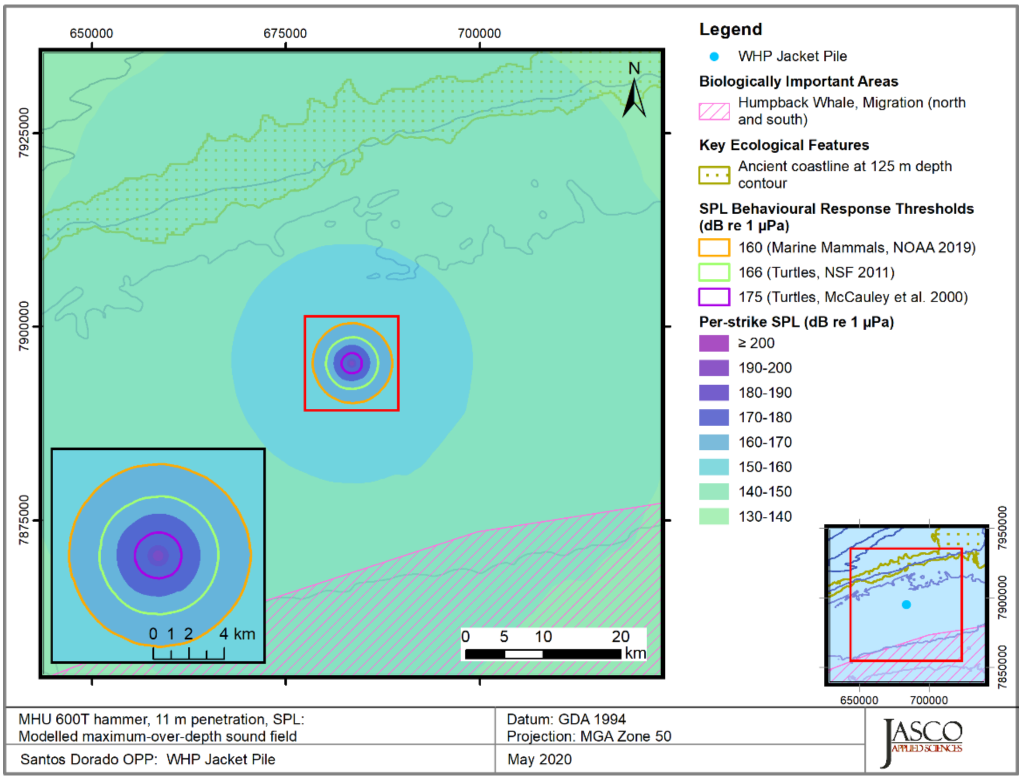

Figure 10. *WHP piling, SPL, 11 m penetration depth*: Sound level contour map, showing maximum-over-depth results. Isopleths for sea turtles (166 and 175 dB re 1 µPa) and marine mammal (160 dB re 1 µPa) behavioural criteria are shown.

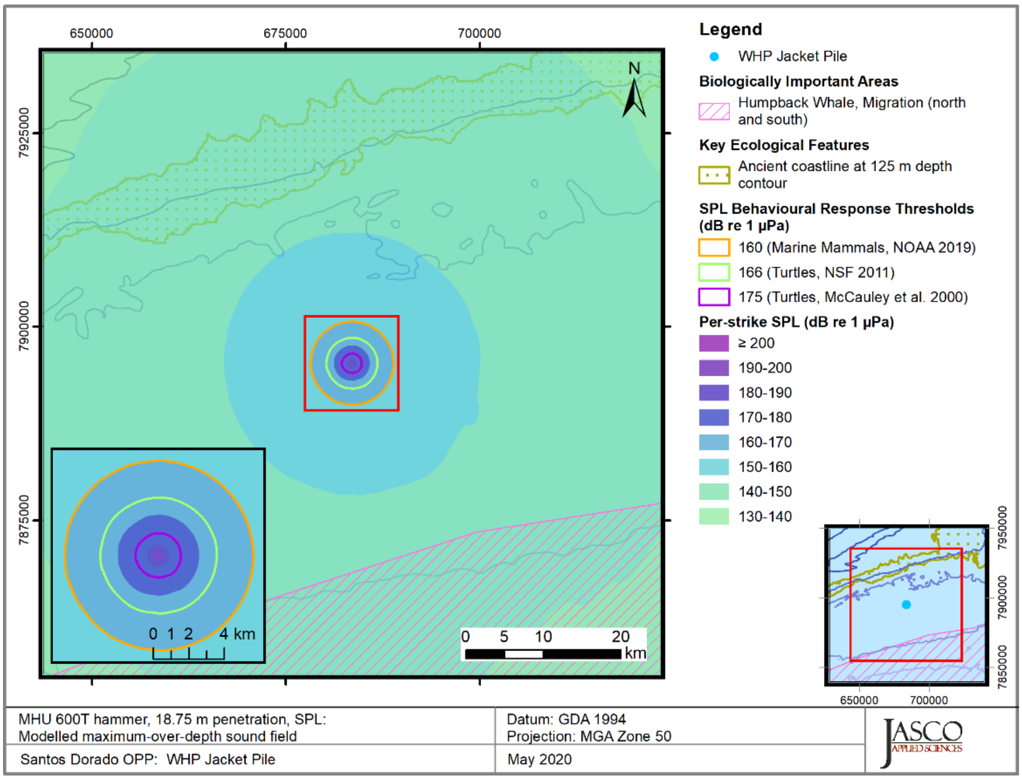

Figure 11. *WHP piling, SPL, 18.75 m penetration depth*: Sound level contour map, showing maximum-over-depth results. Isopleths for sea turtles (166 and 175 dB re 1 µPa) and marine mammal (160 dB re 1 µPa) behavioural criteria are shown.

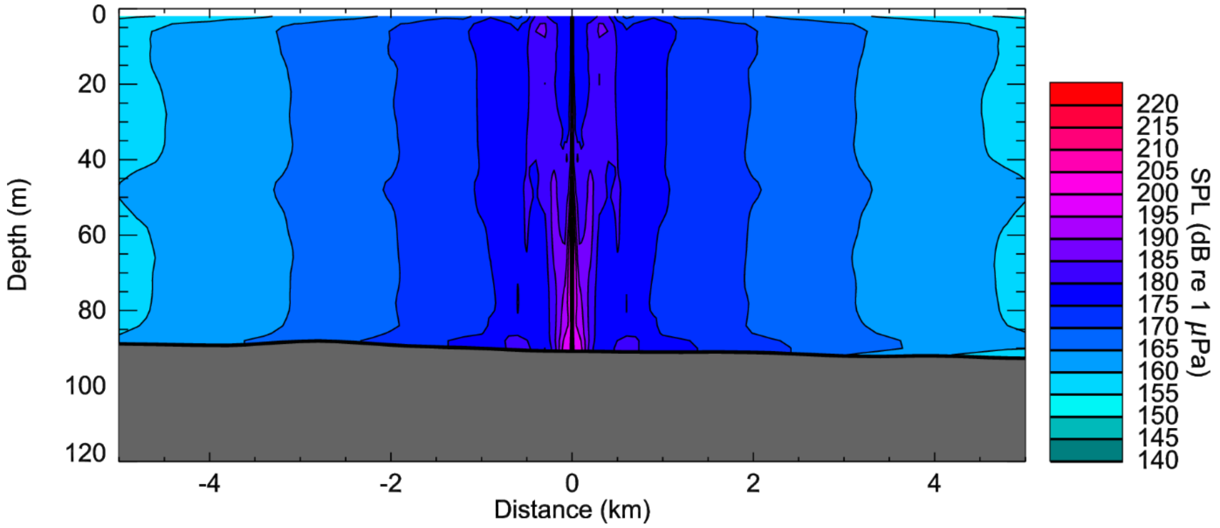

Figure 12. *WHP piling, vertical slice, SPL, 3.5 m penetration depth*: 0–5 km. Levels are shown along a single north-south transect.

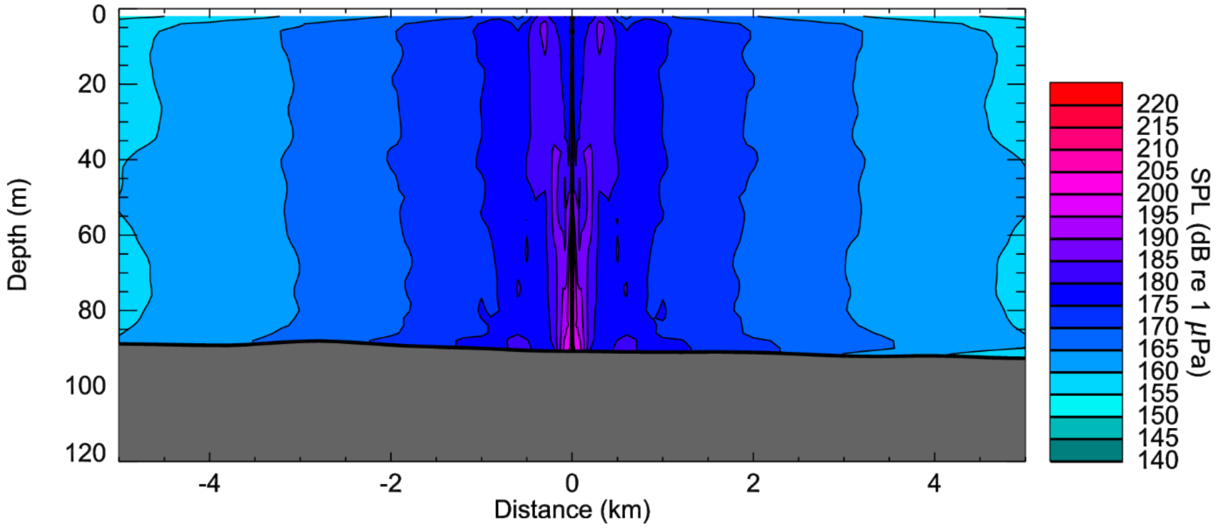

Figure 13. *WHP piling, vertical slice, SPL, 11 m penetration depth*: 0–5 km. Levels are shown along a single north-south transect.

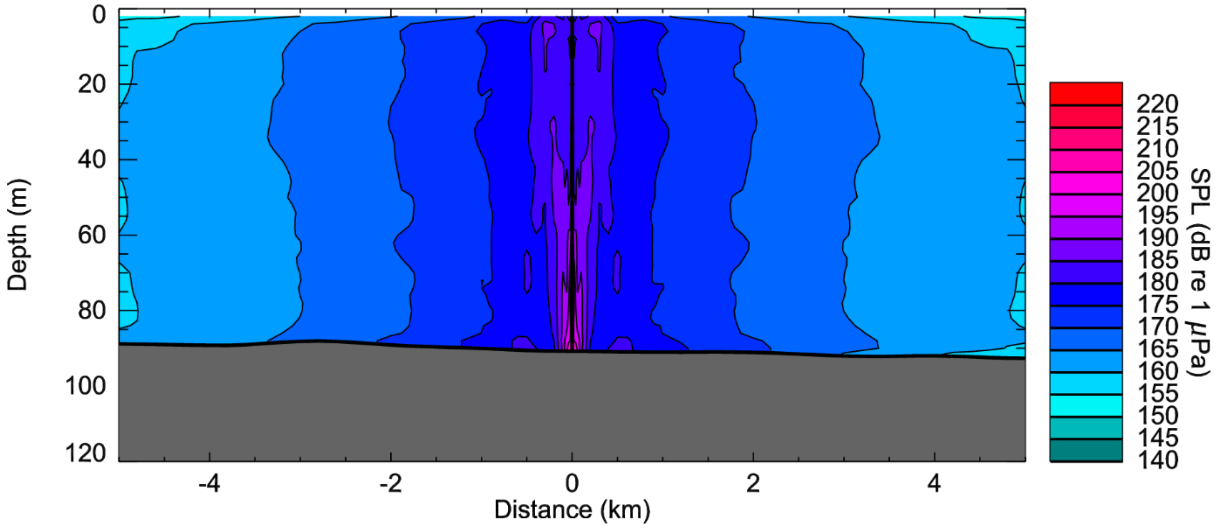

Figure 14. *WHP piling, vertical slice, SPL, 18.75 m penetration depth*: 0–5 km.Levels are shown along a single north-south transect.

Multiple Strike Sound Fields

Table 20 presents the SEL_{24h} results relevant to marine mammals for the proposed pile driving operations for the WHP, while Table 21 shows modelled distances to the cumulative exposure criteria contours for fish, fish eggs and larvae. The sound level contour map for marine mammals and sea turtles is presented in Figure 15, and the map for fish is shown in Figure 16.

Table 20. *WHP piling*: Maximum-over-depth distances (in km) to frequency-weighted SEL_{24h} based PTS and TTS thresholds for marine mammal (Southall et al. 2019) and sea turtles (Finneran et al. 2017)

Hearing group	Threshold for SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s) #	R_{max} (km)	Area (km²)
PTS			
Low-frequency cetaceans	183	5.29	83.2
High-frequency cetaceans	185	–	–
Very High-frequency cetaceans	155	0.54	0.92

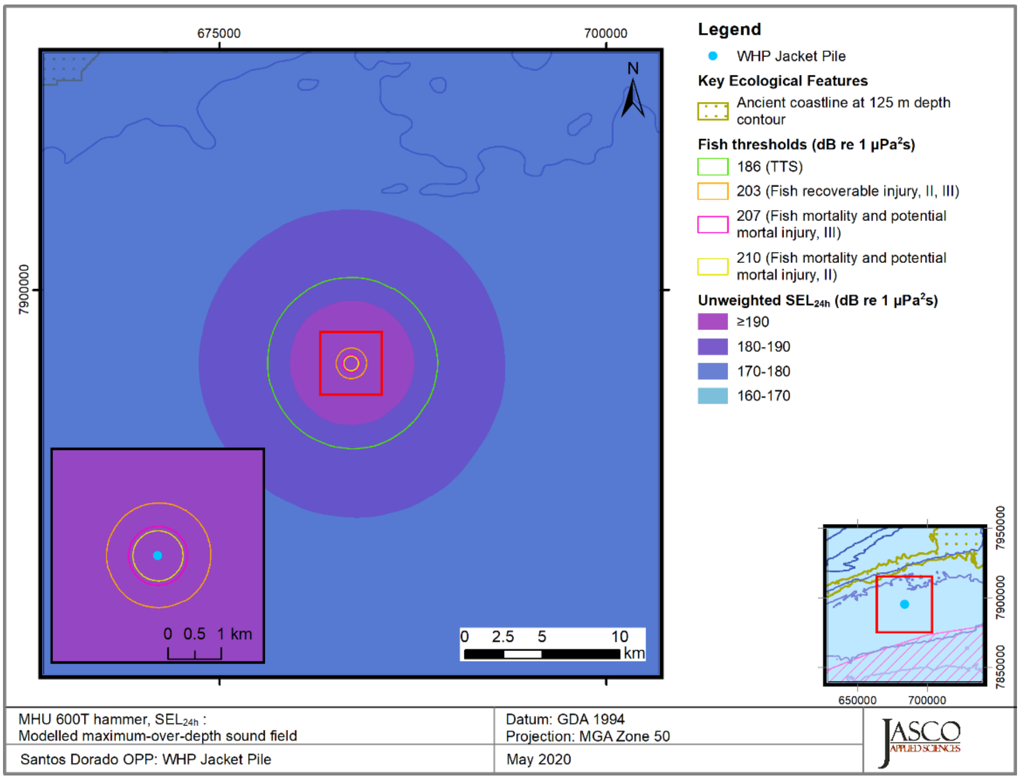

Figure 16. *WHP piling, SEL$_{24h}$*: Sound level contour map showing unweighted maximum-over-depth SEL$_{24h}$ results, along with isopleths relevant to fish injury and TTS.Fish I–No swim bladder; Fish II–Swim bladder not involved with hearing; Fish III–Swim bladder involved with hearing.

4.2. FPSO Anchor Piling

4.2.1. Received levels at 10 m

Since piles are distributed and directional sources, they cannot be accurately approximated by a point source with corresponding source levels (extended detail is provided in Appendix B). It is possible to compare the maximum modelled levels at short distances from the piles. Figure 17 shows the 1/3-octave-band levels for the receiver with the highest SEL at a horizontal range of 10 m for the three modelled penetrations. The levels above 1000 Hz were extrapolated using a 20 dB/decade decay rate to match acoustic measurements of impact pile driving of similarly sized piles (Illingworth & Rodkin 2007, Matuschek and Betke 2009). The modelled results at a distance of 10 m are included to provide results comparable to other pile driving reports and literature, such as Illingworth & Rodkin (2007), and Denes et al. (2016).

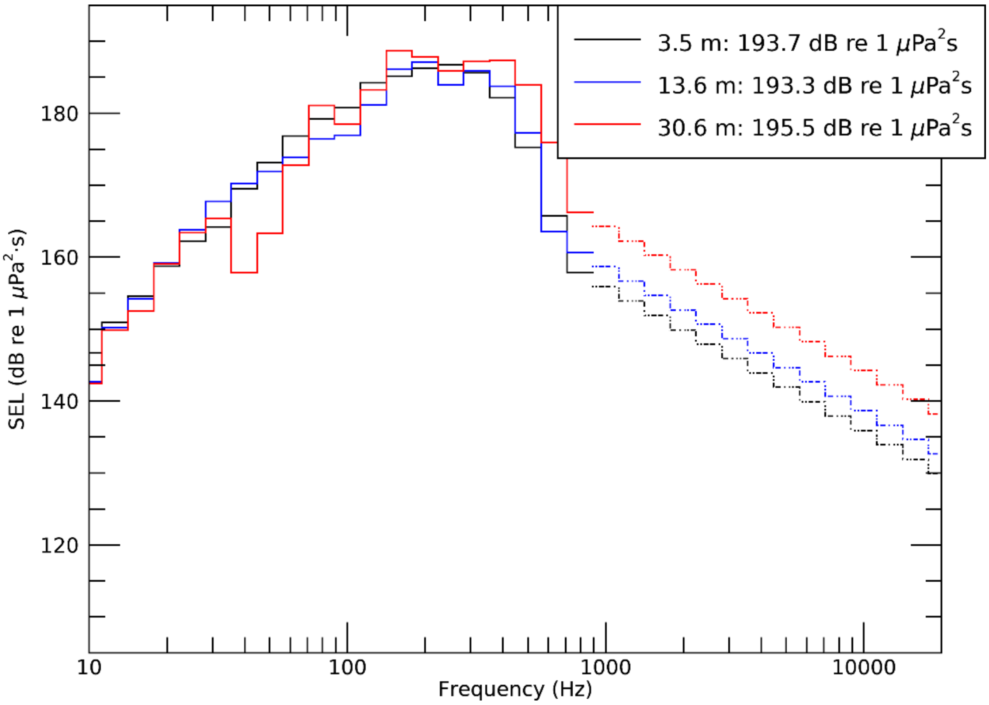

Figure 17. *FPSO anchor piling*: 1/3-octave-band levels for the receiver with highest SEL at 10 m horizontal range for impact pile driving using the MHU 600T hammer, after high-frequency extrapolation (dashes indicate extrapolated portion of the spectrum). Legend items indicate the modelled pile penetration (Table 14) and the broadband SEL in dB re 1 μPa²·s.

4.2.2. Per-strike sound fields

Per-strike results for the proposed pile driving are presented in this section for maximum-over-depth SPL, SEL, and PK (tables in Section 4.1.2.1), maps and sound field vertical slices (Section 4.2.2.2).

4.2.2.1. Tabulated results

Tables 22–26 show the estimated distances for the various applicable per-strike effects criteria and isopleths of interest as maximum-over-depth.

Table 22. *FPSO anchor piling, per-strike SEL:* Maximum (R_{max}) and 95% ($R_{95\%}$) horizontal distances (in km) from the pile to modelled maximum-over-depth isopleths for the MHU 600T hammer.

Per-strike SEL (L_E; dB re 1 µPa²·s)	Penetration depth					
	3.5 m		13.6 m		30.6 m	
	R_{max} (km)	$R_{95\%}$ (km)	R_{max} (km)	$R_{95\%}$ (km)	R_{max} (km)	$R_{95\%}$ (km)
190	0.03	0.03	0.05	0.05	0.02	0.02
180	0.28	0.27	0.23	0.22	0.06	0.06

Fish: Swim bladder not involved in hearing; Swim bladder involved in hearing Fish eggs, and larvae	207	361	288	85

4.2.2.2. Sound field maps and vertical slices

Maps of the per-strike SPL results associated with the three modelled penetration depths for driving the FPSO anchor pile are shown in Figures 18–20 for the MHU 600T hammer. The isopleths for marine mammal behavioural criteria (160 dB re 1 µPa) for each of the three considered penetration depths are also provided. Vertical slice plots for all penetrations are shown in Figures 21–23. Per-strike SEL maps are shown in Appendix G.2.

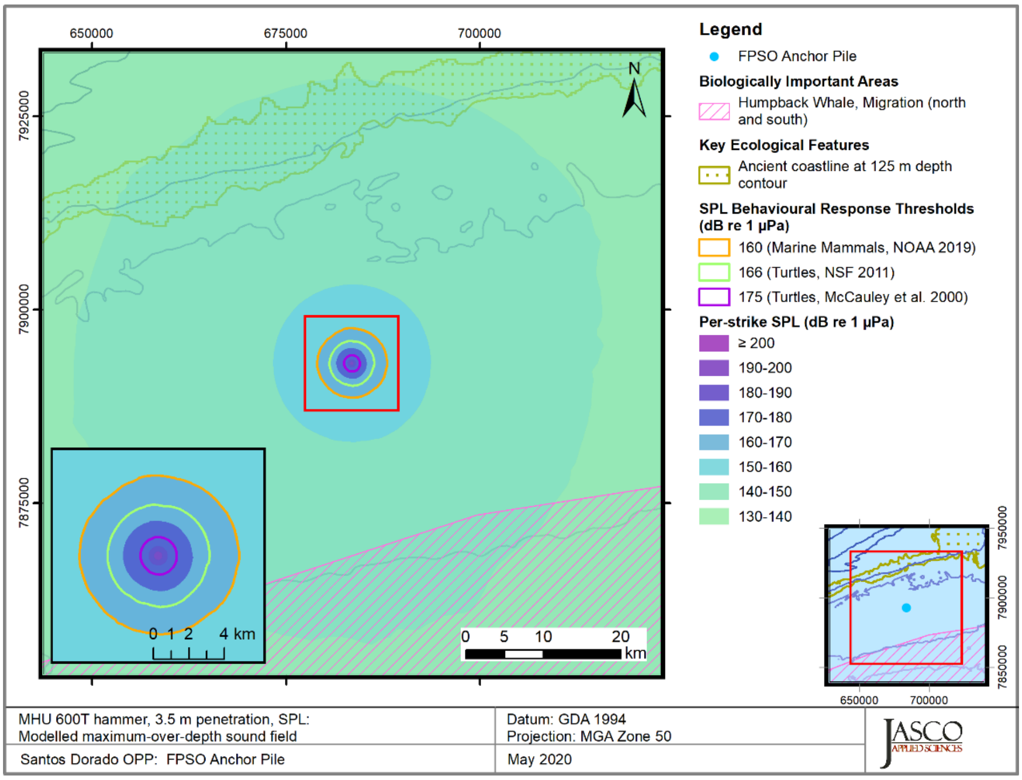

Figure 18. *FPSO anchor piling, SPL, 3.5 m penetration depth*: Sound level contour map, showing maximum-over-depth results. Isopleths for sea turtles (166 and 175 dB re 1 µPa) and marine mammal (160 dB re 1 µPa) behavioural criteria are shown.

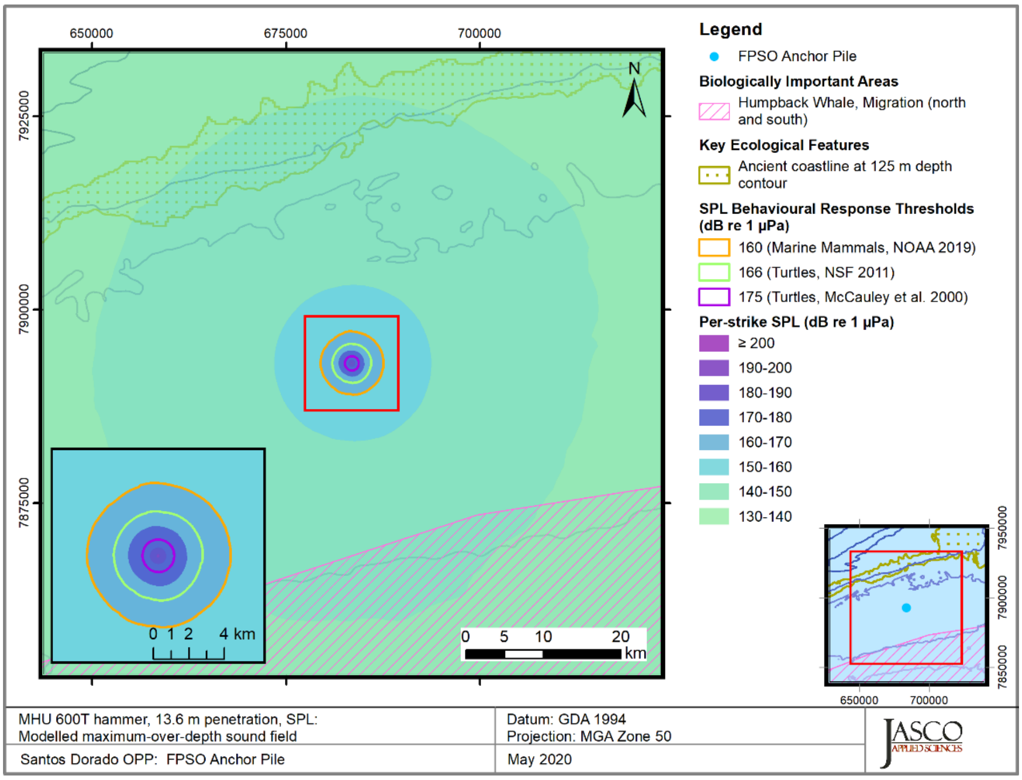

Figure 19. *FPSO anchor piling, SPL, 13.6 m penetration depth*: Sound level contour map, showing maximum-over-depth results. Isopleths for sea turtles (166 and 175 dB re 1 µPa) and marine mammal (160 dB re 1 µPa) behavioural criteria are shown.

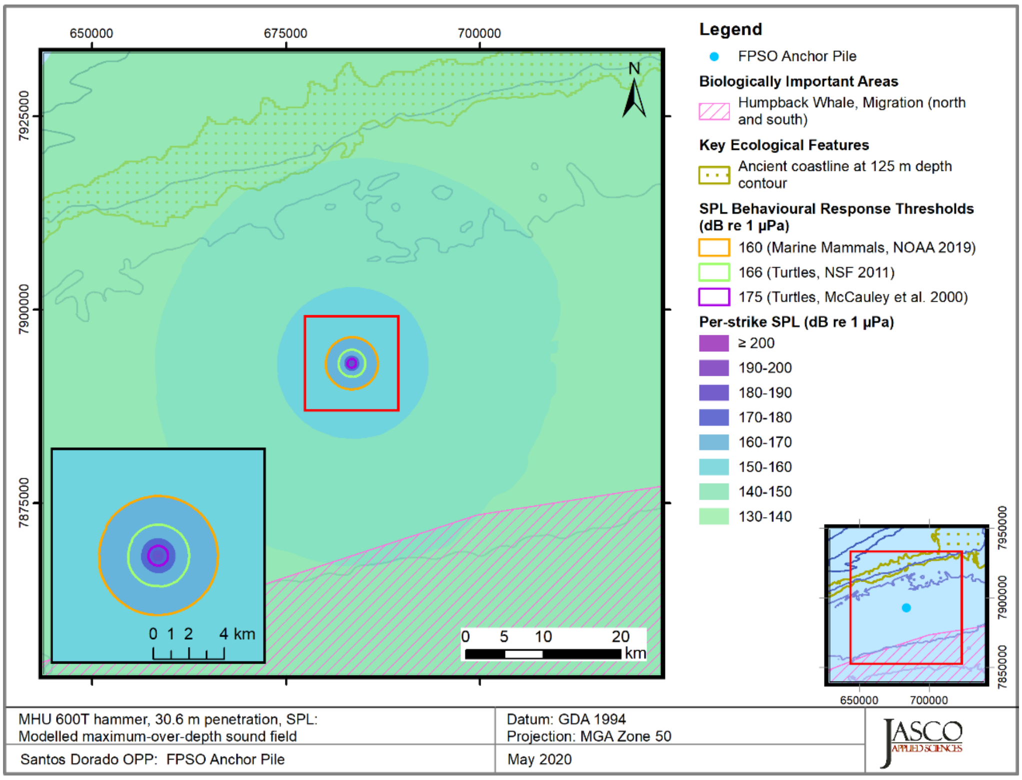

Figure 20. *FPSO anchor piling, SPL, 30.6 m penetration depth:* Sound level contour map, showing maximum-over-depth results. Isopleths for sea turtles (166 and 175 dB re 1 µPa) and marine mammal (160 dB re 1 µPa) behavioural criteria are shown.

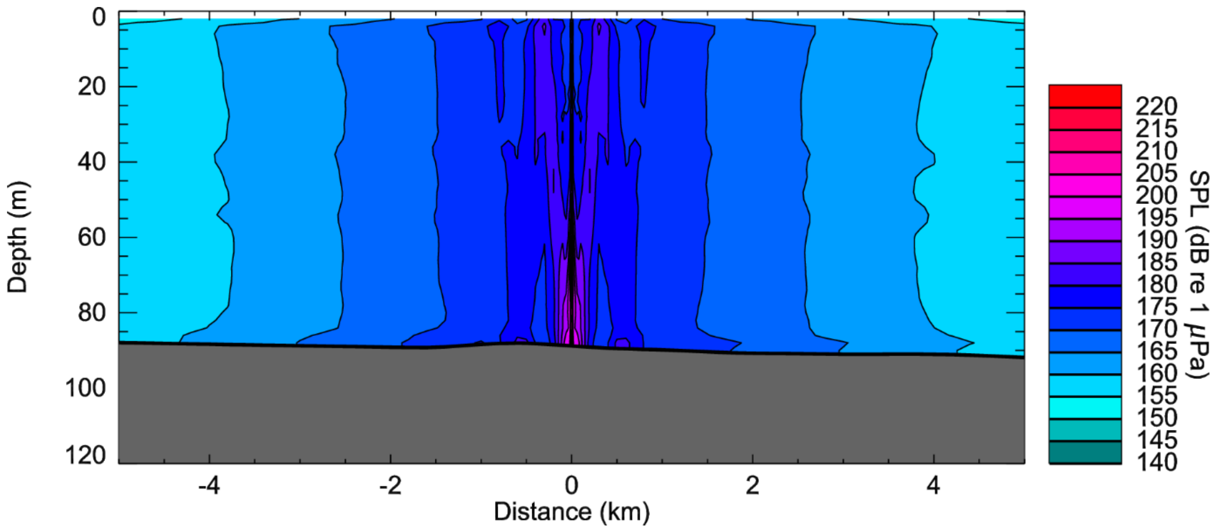

Figure 21. *FPSO anchor piling, vertical slice, SPL, 3.5 m penetration depth*: 0–5 km. Levels are shown along a single north-south transect.

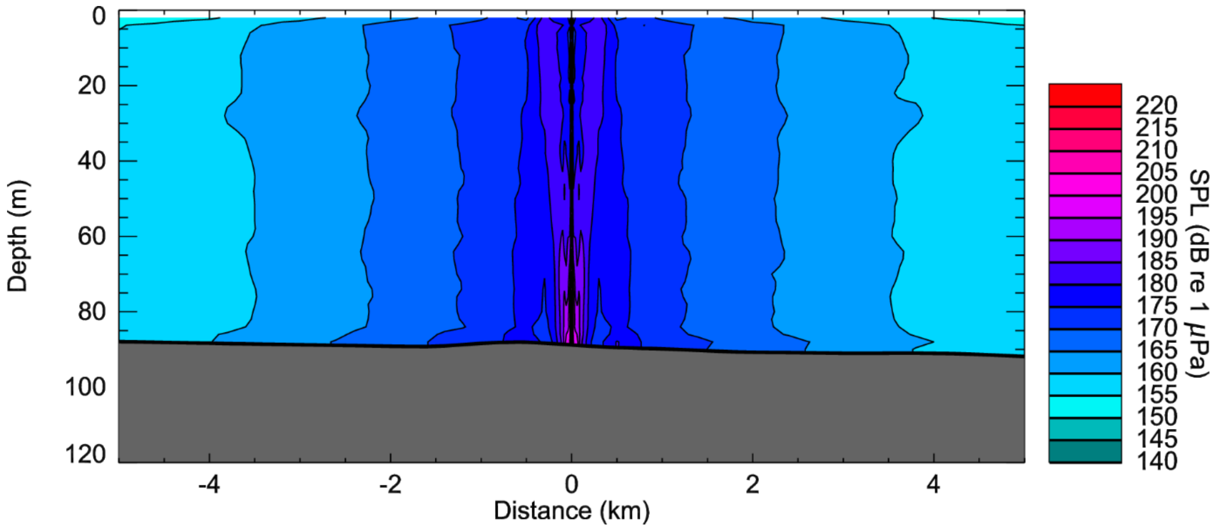

Figure 22. *FPSO anchor piling, vertical slice, SPL, 13.6 m penetration depth*: 0–5 km. Levels are shown along a single north-south transect.

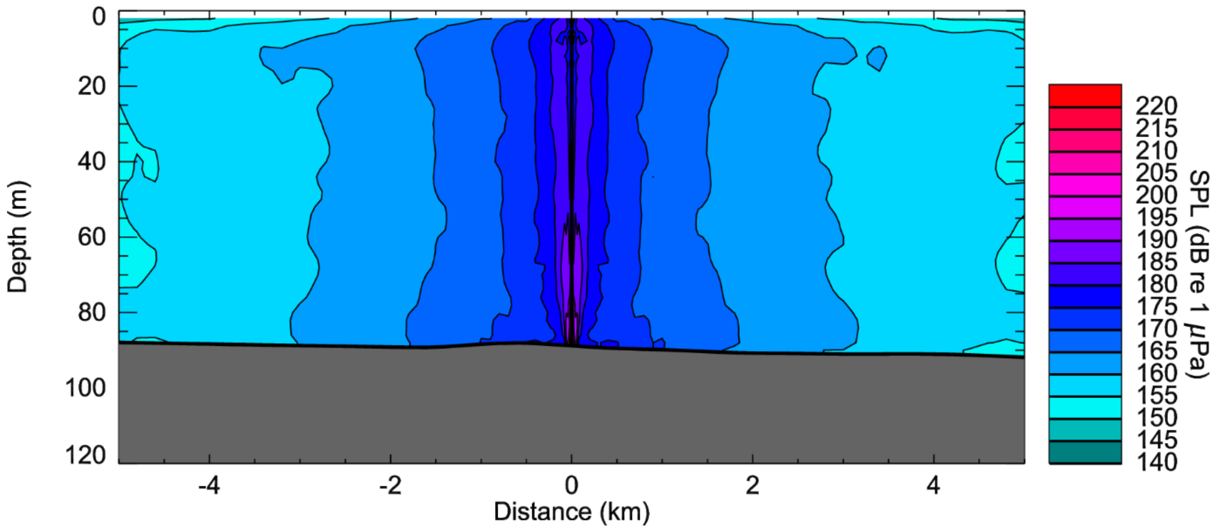

Figure 23. *FPSO anchor piling, vertical slice, SPL, 30.6 m penetration depth*: 0–5 km. Levels are shown along a single north-south transect.

4.2.3. Multiple Strike Sound Fields

Table 27 presents the SEL_{24h} results relevant to marine mammals for the proposed pile driving operations, while Table 29 shows modelled distances to the cumulative exposure criteria contours for fish, fish eggs and larvae. The sound level contour map for marine mammals and sea turtles is presented in Figure 24 and the map for fish is shown in Figure 25.

Table 27. *FPSO anchor piling*: Maximum-over-depth distances (in km) to frequency-weighted SEL_{24h} based PTS and TTS thresholds for marine mammal (Southall et al. 2019) and sea turtles (Finneran et al. 2017).

Hearing group	Threshold for SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s) #	R_{max} (km)	Area (km²)
PTS			
Low-frequency cetaceans	183	5.84	104
High-frequency cetaceans	185	0.03	0.001
Very High-frequency cetaceans	155	1.04	2.68
Sea turtles	204	0.68	1.44
TTS			
Low-frequency cetaceans	168	28.2	2182
High-frequency cetaceans	170	0.36	0.41
Very High-frequency cetaceans	140	4.27	54.1
Sea turtles	189	3.98	48.7

A dash indicates the threshold is not reached within the limits of the modelling resolution (20 m).
Frequency weighted.

Table 28. FPSO anchor piling: Ensonified areas (km²) corresponding to maximum-over-depth low-frequency cetacean PTS and TTS thresholds (Southall et al. 2019).

Threshold	Area ensonified (km²)	Area of HW migration BIA ensonified (km²)
Low-frequency cetaceans PTS	104	0
Low-frequency cetaceans TTS	2182	39

Table 29. *FPSO anchor piling*: Maximum-over-depth distances (in km) to SEL_{24h} based fish criteria. Fish I–No swim bladder; Fish II–Swim bladder not involved with hearing; Fish III–Swim bladder involved with hearing.

Marine fauna group	Threshold for SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	Maximum-over-depth	
		R_{max} (km)	Area (km²)
Mortality and potential mortal injury			
I	219	0.09	0.02
II, fish eggs and fish larvae	210	0.39	0.48
III	207	0.52	0.84
Fish recoverable injury			
I	216	0.23	0.17
II, III	203	0.96	2.79

I, II, III	186	5.88	105.6

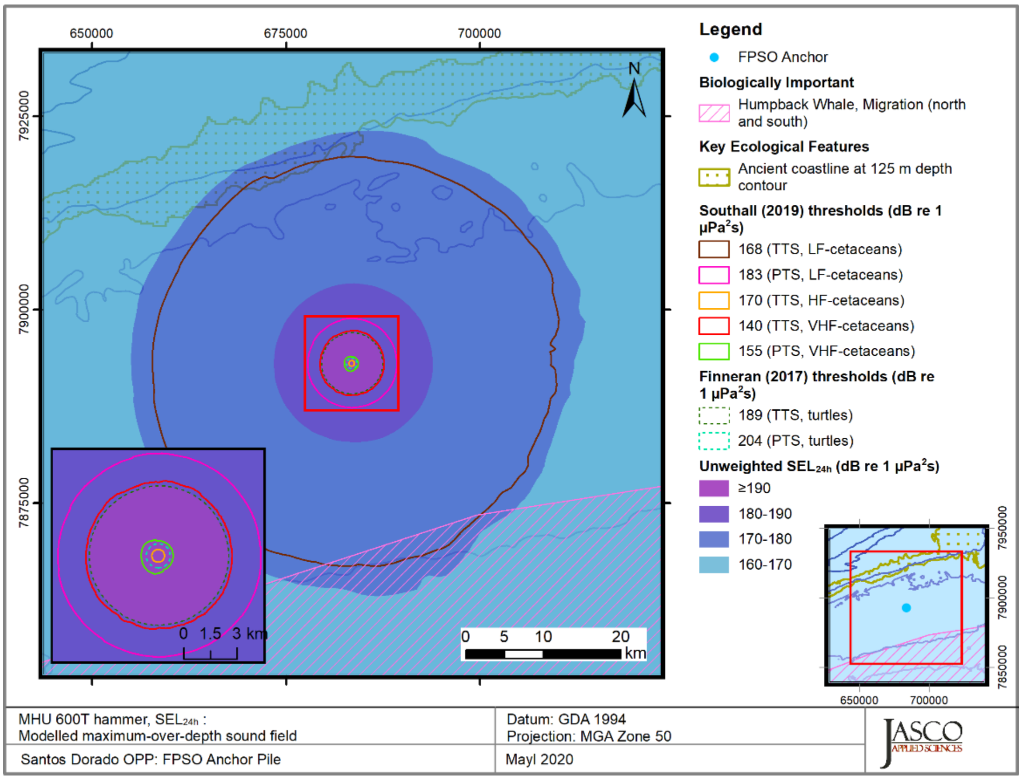

Figure 24. *FPSO anchor piling, SEL_{24h}*: Sound level contour map showing unweighted maximum-over-depth SEL_{24h} results, along with isopleths for low-, high-, and very-high-frequency cetaceans and sea turtles. Threshold contour for high-frequency cetacean PTS is too small to be displayed on a map. Refer to the radii in Table 27 for distances.

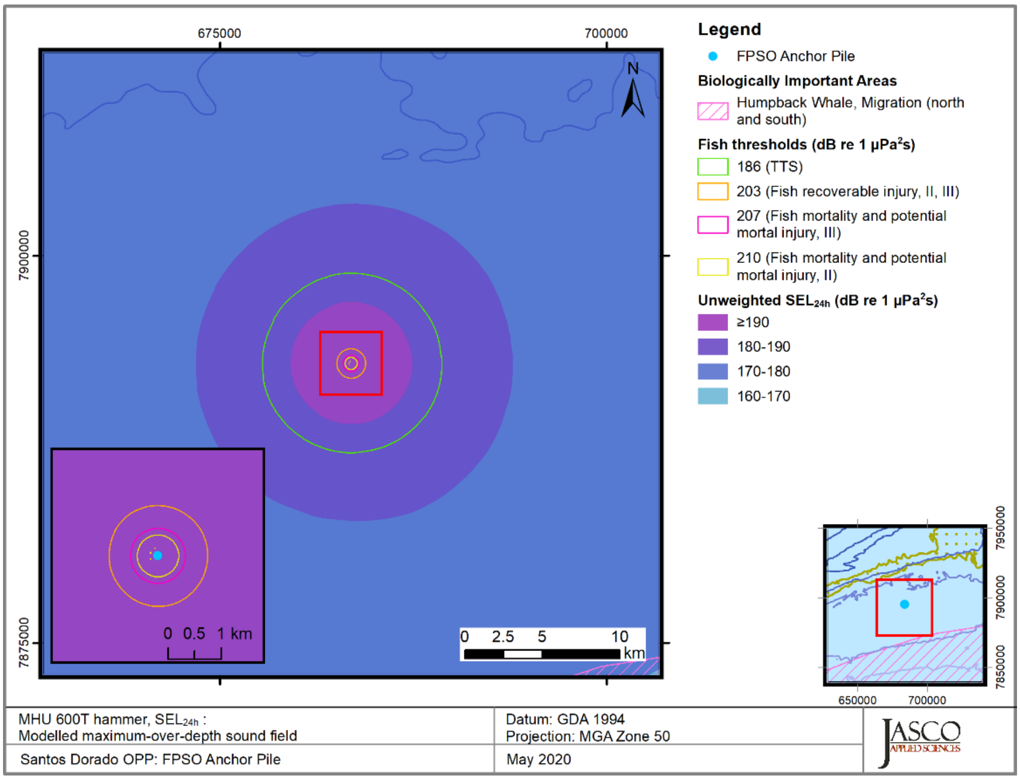

Figure 25. *FPSO anchor piling, SEL_{24h}*: Sound level contour map showing unweighted maximum-over-depth SEL_{24h} results, along with isopleths relevant to fish injury and TTS. Fish I–No swim bladder; Fish II–Swim bladder not involved with hearing; Fish III–Swim bladder involved with hearing.

4.3. Vertical Seismic Profiling (VSP)

4.3.1. Acoustic Source Levels and Directivity

AASM (Section 3.2.1) was used to predict the horizontal and vertical overpressure signatures and corresponding power spectrum levels for the seismic source, with results provided in Appendix C.2 along with the horizontal directivity plots.

Table 30 shows the PK and per-pulse SEL source levels in the horizontal-plane perpendicular to the sagittal plane of the array, parallel to the sagittal plane of the array, and vertical directions. The vertical source level that accounts for the “surface ghost” (the out of phase reflected pulse from the water surface) is also presented to make it easier to compare the output of other seismic source models.

Figure C-2 shows overpressure signatures and corresponding power spectrum levels for the source. The signature consists of a strong primary peak, related to the initial release of high-pressure air, followed by a series of pulses associated with bubble oscillations. Most energy was produced at frequencies below 300 Hz. Frequency-dependent peaks and nulls in the spectrum result from interference among airguns in the source and correspond with the volumes and relative locations of the airguns to each other.

Table 30. Far-field source level specifications for the 750 in3 source, for a 5 m source depth. Source levels are for a point-like acoustic source with equivalent far-field acoustic output in the specified direction. Sound level metrics are per-pulse and unweighted.

Direction	Peak source pressure level ($L_{S,pk}$; dB re 1 μPa m)	Per-pulse source SEL ($L_{S,E}$; dB 1 μPa²m²s)	
		10–2000 Hz	2000–25000 Hz
Sagittal Perpendicular	239.2	214.5	168.8
Sagittal Parallel	239.4	214.5	165.8
Vertical	239.2	214.5	173.6
Vertical (surface affected source level)	239.3	216.1	176.6

4.3.3.1. Sound field maps

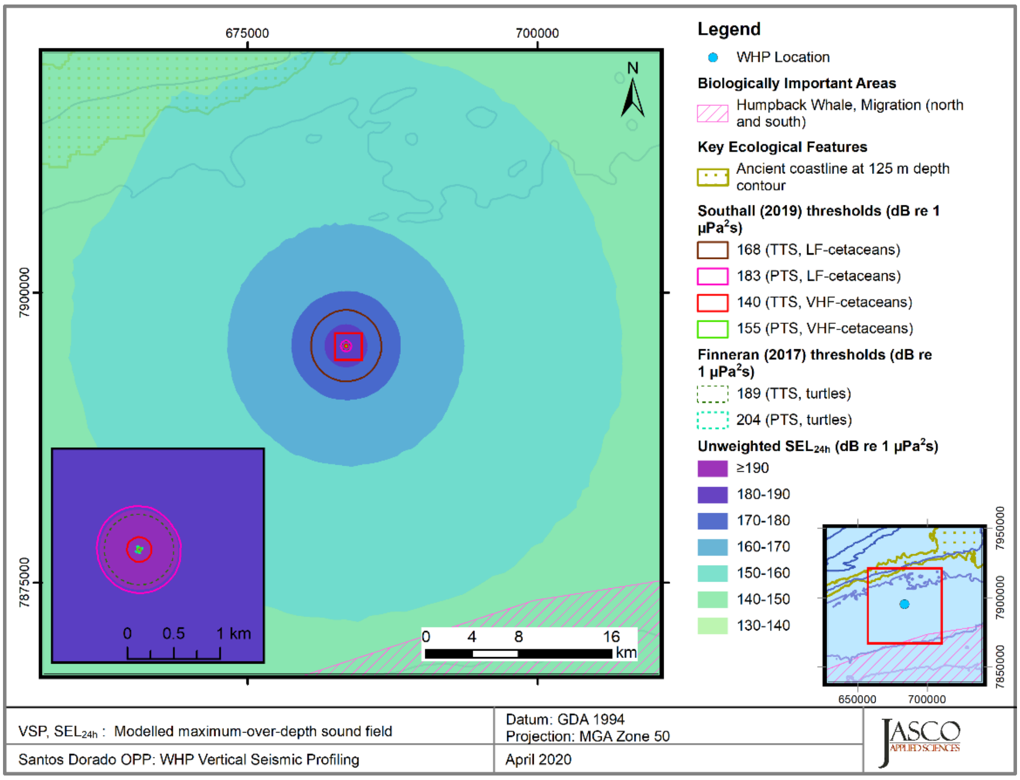

Figure 28. *VSP, multiple-pulse SEL*: Sound level contour map showing unweighted maximum-over-depth SEL_{24h} results for 300 VSP impulses, along with isopleths for low-, and very-high-frequency cetaceans and sea turtles. Refer to the radii tables in Section 4.3.3 for distances.

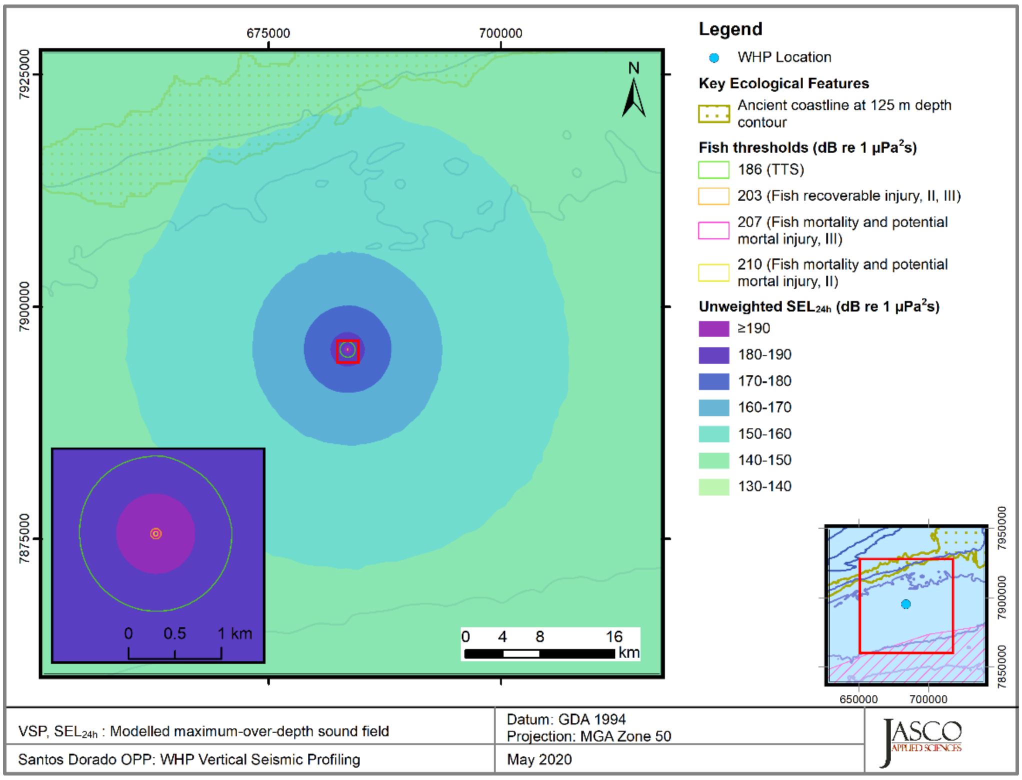

Figure 29. *VSP, multiple-pulse SEL*: Sound level contour map showing unweighted maximum-over-depth SEL_{24h} results for 300 VSP impulses, along with the isopleths for fish thresholds from Popper et al. (2014). Where contours are too small to identify on the map refer to the radii in Table 36 for distances. Mortality and recoverable injury thresholds for Fish I were not reached.

4.4. Vessel Noise

Sound field results are presented for SPL (Tables 37 and Table 38) and SEL_{24h} (Tables 39) for the modelling scenarios involving:

- FPSO thruster noise for an FPSO under dynamic positioning (DP).
- FPSO operational noise for an FPSO under normal operating conditions.
- An Offshore Support Vessel (OSV) supporting offtake operations
- FPSO operational noise during offtake, represented by:
  - The FPSO under dynamic positioning (DP).
  - The FPSO under DP, with a noiseless condensate tanker, and the OSV supporting the offtake.

5. Discussion and Summary

An analysis of seasonal sound speed profiles, the results of which are presented in Appendix F.3.2, indicated that July was the month most conducive to sound propagation due to the presence of an upward refracting layer near the sea surface; as such it was selected to ensure a conservative estimation of distances to received sound level thresholds. Modelling also accounted for site-specific bathymetric variations (Appendix F.3.1) and local seabed geoacoustic properties (Appendix F.3.3).

As the FPSO and WHP modelled sites are situated on the central North West Shelf, variations in bathymetry were generally gradual within the modelled area. Any variations in the bathymetry had a small effect on the predicted sound field footprints as manifested in the generally symmetric sound field footprints. This applied to all source types considered.

5.1. Ranges to exposure thresholds

For the results and summary tables presented above and below where a dash is used in place of a horizontal distance, these thresholds may or may not be reached. Due to the discretely sampled 20 m radial increments of the modelled sound fields, distances to those levels could not be estimated to the computational resolution of the closest step to the source. It is likely that in the case of per-pulse or per-strike SPL, SEL, PK, and continuous SPL some thresholds would be reached at distances between the source and the modelled horizontal resolution (20 m); the injury thresholds based on accumulated SEL on the other hand may not be reached at any range due the species specific frequency weighing functions. A dash therefore is an indication that effect levels for the associated metric may only be reached within a very close proximity to a given source, if at all.

5.2. Pile Driving

5.2.1. Acoustic propagation

This study predicted underwater sound levels associated with impact driving of subsea piles for the WHP and seabed anchor for FPSO facility.

For the WHP jacket piles, the underwater sound field was modelled for 50 m long piles with a 3.0 m diameter with 55 mm wall thickness; The WHP jacket piles will be driven a total of 21.5 m into the seabed. The broadband sound energy at 10 m for each penetration depth ranged from 193.7 – 194.4 dB re 1 µPa^2·s with the peak sound energy concentrated in the frequency range 100 to 400 Hz (Figure 8), with levels from the pile at the 18.75 m penetration depth having the highest energy.

For the FPSO anchor piles, the underwater sound field was modelled for 40 m long piles with a 2.5 m diameter with 100 mm wall thickness. The FPSO anchor piles will be driven completely into the seabed. The broadband sound energy at 10 m for each penetration depth ranged from 193.7 to 195.5 dB re 1 µPa^2·s with the peak sound energy concentrated in the frequency range 100 to 400 Hz (Figure 17), with levels from the pile at the 30.6 m penetration depth having the highest energy.

Noise emissions from pile driving were considered here to be cylindrically isotropic (i.e., omnidirectional in the horizontal plane). As such, variations in noise that propagates across azimuths are attributed to the bathymetry alone. When the hammer strikes the pile, noise propagates into the water as a downward Mach cone (see Appendix B). A portion of the energy from the strike is also reflected at the pile bottom, generating an upward Mach cone. This cycle of downward propagation, reflection, and upward propagation occurs multiple times per strike. At close range from the pile, noise levels are determined by the summation of Mach cones, which might add constructively (i.e., their summation results in a total wave with higher amplitude than the original ones) or destructively (i.e., wavefronts can cancel each other, resulting in lower amplitudes). The way in which Mach cones combine with each other is strongly dependent on their frequency content, which is determined by the hammer forcing function and the pile dimensions.

Due to the relation between the speed of sound in steel (~5000 m/s) relative to the speed of sound in the water (~1527 m/s at the depth of the pile), the Mach cone propagates away from the pile and impinges the seabed at an angle of ~17°. The first bottom bounce occurs within 15 m from the pile, and the first surface bounce occurs within 27 m from the pile. As shown in Figures 12–14 ,21–22 the Mach cone corresponding to the shallowest pile penetration introduces substantial energy that propagates through the water column, compared to the 30.6 m pile penetration for the FPSO anchor pile scenario in Figure 23, for which underground sound propagation tends to dominate near the pile.

The modelling of the three penetration depths for each pile provides a detailed quantification of the associated sound levels for each penetration. The distances to per-strike isopleths are generally farthest when most of the pile is in the water column, and distances are shortest at the end of piling when most of the pile is buried in the sediment. This is despite the per-strike pile penetration being less during the final stages of driving and the increased resistance generating stronger stress-wave reflections at the pile toe.

For criteria based on SEL_{24h} metrics, the ranges above must be considered in context of the duration of operations. One pile will be driven per day; therefore, the corresponding sound level is denoted as SEL_{24h}. However, the estimated time for driving a single pile was 1.6 h for the WHP anchor piles and 4.7 h for FPSO anchor piles (Table 14). The SEL_{24h} is a cumulative metric that reflects the dosimetric impact of noise levels within the driving period and assumes that an animal is consistently exposed to such noise levels at a fixed position. The radii that correspond to SEL_{24h} typically represent an unlikely worst-case scenario for SEL-based exposure since. More realistically, marine fauna (mammals, sea turtles or fish) would not stay in the same location or at the same range for an extended period. Therefore, a reported radius associated with the accumulated SEL criteria does not mean that any animal travelling within this radius of the source *will* be injured, but rather that it *could* be injured if it remained in that range for the entire period of driving (1.6 and 4.7 hours).

5.2.2. Marine mammals

- NOAA (2019) acoustic threshold for behavioural response in marine mammals: Distances to the SPL threshold of 160 dB re 1 µPa are between 3.4–5.4 km, depending on the penetration depth and type of pile being driven. The maximum distance for the WHP jacket pile is 5.4 km, while maximum distance for the FPSO anchor pile is 4.59 km (Tables 17 and 24).
- Southall et al. (2019) criteria for marine mammal Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): The assessment considers both metrics within the criteria (PK and SEL), with SEL assessed here for a single pile within a 24 h period, i.e., a single pile per day. The metric with the longest distance must be applied, and these maximum distances along with the relevant metric are summarised in Table 40.

Table 40. *Pile driving*: Maximum-over-depth distances (in km) to marine mammal PTS and TTS thresholds from Southall et al. (2019). PK results are in Tables 18 and 25 while those for SEL_{24h} are in Tables 20 and 27.

Hearing group	WHP jacket pile		FPSO anchor pile	
	Metric associated with longest distance to injury criteria	R_{max} (km)	Metric associated with longest distance to injury criteria	R_{max} (km)
PTS				
Low-frequency cetaceans	SEL_{24h}	5.29	SEL_{24h}	5.84
High-frequency cetaceans	SEL_{24h}	–	SEL_{24h}	0.03
Very-high-frequency cetaceans	PK	0.55	SEL_{24h}	1.04
TTS				
Low-frequency cetaceans	SEL_{24h}	22.6	SEL_{24h}	28.2
High-frequency cetaceans	SEL_{24h}	0.29	SEL_{24h}	0.36
Very-high-frequency cetaceans	SEL_{24h}	2.78	SEL_{24h}	4.27

A dash indicates the threshold was not reached within the limits of the modelling resolution (20 m).

5.2.3. Sea turtles

- NMFS criterion for behavioural response (SPL of 166 dB re 1 µPa) and a criterion for increased behavioural disturbance (SPL of 175 dB re 1 µPa) (Moein et al. 1995, McCauley et al. 2000b, McCauley et al. 2000a): Maximum distances are associated with the shallowest penetration of 3.5 m for both piling locations, with the maximum distances summarised in Table 41.
- Finneran et al. (2017) criteria for sea turtle Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): The assessment considers both metrics within the criteria (PK and SEL), with SEL assessed here for a single pile within a 24 h period, i.e., a single pile per day. The metric with the longest distance must be applied, and these maximum distances along with the relevant metric are summarised in Table 42.

Table 41. *Pile driving*, turtle behavioural response thresholds, SPL: Maximum (R_{max}) and 95% ($R_{95\%}$) horizontal distances (in km) from the pile to modelled maximum-over-depth isopleths, maximum across all three modelled penetration depths. Results are presented in Tables 17 and 24.

Threshold	WHP		FPSO	
	R_{max} (km)	$R_{95\%}$ (km)	R_{max} (km)	$R_{95\%}$ (km)
Turtle behaviour, SPL: 166 dB re 1 µPa (NSF 2011)	3.51	3.36	2.91	2.79
Turtle disturbance, SPL: 175 dB re 1 µPa (McCauley et al. 2000b, 2000a)	1.39	1.34	1.07	1.02

Table 42. *Pile driving*: Maximum-over-depth distances (in km) to turtle PTS and TTS thresholds (Finneran et al. 2017). PK thresholds were not reached within the limits of the modelled resolution while those for SEL_{24h} are in Tables 20 and 27.

Threshold	WHP jacket pile		FPSO anchor pile	
	Metric associated with longest distance to injury criteria	R_{max} (km)	Metric associated with longest distance to injury criteria	R_{max} (km)
PTS	SEL_{24h}	0.72	SEL_{24h}	0.68
TTS	SEL_{24h}	4.11	SEL_{24h}	3.98

5.2.4. Fish, fish eggs, and fish larvae

The modelling study assessed the ranges for quantitative criteria from Popper et al. (2014) associated with mortality and potential mortal injury and impairment in the following:

- Fish without a swim bladder (also appropriate for sharks in the absence of other information)
- Fish with a swim bladder not used for hearing
- Fish that use their swim bladders for hearing
- Fish eggs, and fish larvae

Considering both per-strike modelled penetrations and associated SEL_{24h} scenario, along with both PK and SEL_{24h} metrics, in line with the conditions of the criteria, the maximum distances are summarised in Table 43.

Table 43. Summary of maximum fish, fish eggs, and larvae injury and TTS onset distances for single impulse and SEL_{24h} modelled scenarios (PK values from Tables 18 and 25, SEL_{24h} values from Tables 21 and 29).

Relevant hearing group	Injury criteria	WHP		FPSO	
		Metric associated with longest distance to injury criteria	R_{max} (km)	Metric associated with longest distance to injury criteria	R_{max} (km)
Fish: No swim bladder	Injury	PK	0.17	PK	0.13
	TTS	SEL_{24h}	5.59	SEL_{24h}	5.88
Fish: Swim bladder not involved in hearing	Injury	SEL_{24h}	0.47	SEL_{24h}	0.39
	TTS	SEL_{24h}	5.59	SEL_{24h}	5.88
Fish: Swim bladder involved in hearing	Injury	SEL_{24h}	0.56	SEL_{24h}	0.52
	TTS	SEL_{24h}	5.59	SEL_{24h}	5.88
Fish eggs and larvae	Injury	SEL_{24h}	0.47	SEL_{24h}	0.39

5.3. VSP

5.3.1. Acoustic propagation

This study predicted underwater sound levels associated with VSP sources at the WHP. The underwater sound field was modelled for a 750 in^3 seismic source array deployed at depth 5 m (Appendix C). Since the VSP source is mostly isotropic (vertically and horizontally), sound propagation for this source is driven by gradual changes in bathymetric features.

5.3.2. Marine mammal injury and behaviour

- NOAA (2019) acoustic threshold for behavioural response in marine mammals: The maximum distance to the SPL threshold of 160 dB re 1 µPa was 2.42 km from the centre of the VSP array.
- Southall et al. (2019) criteria for marine mammal Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): The SEL_{24h} threshold distance considers multiple impulses within a 24 h period, ranging from 1 to 300. The applicable metric from the criteria, associated with the longest distance associated with either metric, depends upon the number of impulses with the 24 h. The ranges presented are based upon no more than 300 impulses within 24 h. A reported radius for SEL_{24h} criteria does not mean that marine mammals travelling within this radius of the source *will* be injured, but rather that an animal *could* be exposed to the sound level associated with effect (either PTS or TTS) if it remained in that location for either 24 hours or the duration of the activity if less. Results are presented in Tables 33 and 35.
    - For low-frequency cetaceans, the PTS and TTS thresholds associated with the PK metric were predicted to be less than 20 m from the centre of the acoustic source, otherwise the PTS and TTS ranges were determined by SEL_{24h}, with the maximum distances reached at 470 m for PTS and 3.1 km for TTS.
    - PTS and TTS are not predicted to occur for high-frequency cetaceans.
    - For PTS in very high-frequency cetaceans, the PK metric was always associated with the longest range (63 m), as was the case for TTS (241 m).

5.3.3. Sea turtles

- Finneran et al. (2017) criteria for sea turtle Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): The SEL_{24h} threshold distance considers multiple impulses within a 24 h period, ranging from 1 to 300. Similarly to marine mammals, the reported radii for SEL_{24h} criteria do not mean that sea turtles travelling within this distance of the source will be injured, but rather that an animal could be exposed to the sound level associated with effect (TTS) if it remained in that location for either 24 h or the duration of the activity if less.
    - Within the range of considered impulses (1–300), the PTS threshold was first exceeded at a maximum distance of 30 m when considering the SEL_{24h} criteria for 150 impulses. The PK threshold may be exceeded at distances less than 20 m from the centre of the acoustic source, if at all. Refer to Tables 33 and 35.
    - While the TTS criterion due to the PK metric was not exceeded, depending upon the number of impulses the TTS SEL_{24h} criterion may be exceeded at a maximum distance of 380 m for 300 impulses.
- The distances to where the NMFS criterion (NSF 2011) for behavioural effects in sea turtles of sea turtles of 166 dB re 1 µPa (SPL) and the 175 dB re 1 µPa (SPL) McCauley et al. (2000b), McCauley et al. (2000a) could be exceeded are summarised in Table 44.

Table 44. Distances to turtle behavioural response criteria (from Table 32)

Threshold	R_{max} (km)	$R_{95\%}$ (km)
Turtle behaviour, SPL: 166 dB re 1 µPa (NSF 2011)	1.22	1.18
Turtle behaviour, SPL: 175 dB re 1 µPa (McCauley et al. 2000b, 2000a)	0.38	0.37

5.3.4. Fish, fish eggs, and fish larvae

- This modelling study assessed the ranges for quantitative criteria based on Popper et al. (2014) and considered both PK (seafloor and water column) and SEL_{24h} metrics associated with mortality and potential mortal injury and with impairment in the following groups:
  - Fish without a swim bladder (also appropriate for sharks in the absence of other information);
  - Fish with a swim bladder that do not use it for hearing;
  - Fish that use their swim bladders for hearing; and
  - Fish eggs and fish larvae.
- Sound levels at the seafloor do not exceed any of the criteria (Table 34).
- Based on PK metrics, acoustic injury could be sustained within a horizontal distance less than 20 m from the centre of the VSP source for fish without a swim bladder, and within a maximum horizontal distance of 37 m for fish with a swim bladder, fish eggs, and fish larvae (Table 33).
- Within the range of considered impulses (1–300), the distance to the threshold for the SEL_{24h} metric for injury was first reached at a maximum distance of 50 m for 200 impulses(Table 36).

5.3.5. Sponges and Coral

To assist with assessing the potential effects on these receptors, the following have been determined:

- The PK sound level at the seafloor estimated by modelling directly underneath the VSP source remained below the no effect sound level for sponges and coral of 226 dB re 1 µPa PK (Heyward et al. 2018).

5.4. Vessel Noise (FPSO and OSV)

5.4.1. Acoustic propagation

This study predicted underwater sound levels associated with the operations of an FPSO with and without DP operating, and an OSV near the FPSO (Sections 3.2) plus a noiseless condensate tanker.. Minor variation in the sound field footprint were caused by gradual changes in bathymetric features. Scenarios where the FPSO was under DP produced the largest isopleth distances, this is expected due to the significantly higher source levels for the vessel under DP than not (Section 3.3.1).

5.4.2. Marine mammal injury and behaviour

- Southall et al. (2019) criteria for marine mammal Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): The criteria were assessed for a 24 h period, and the maximum distances to PTS are summarised in Table 45
- NOAA (2019) acoustic threshold for behavioural response in marine mammals: The maximum distances to the SPL threshold of 120 dB re 1 µPa for each scenario are summarised in Table 46

Table 45. *Vessels, marine mammal SEL_{24h} thresholds*: Maximum (R_{max}) horizontal distances (km) from the vessels to modelled maximum-over-depth marine mammal PTS threshold from Southall et al. (2019).

Hearing group	Threshold for PTS, SEL_{24h} (dB re 1 µPa²·s)	Distance R_{max} (km)			
		FPSO on DP	FPSO without DP	OSV	Offtake operations*
Low-frequency cetaceans	199	0.07	–	0.03	0.08
High-frequency cetaceans	198	–	–	–	–
Very-high-frequency cetaceans	173	0.21	–	0.05	0.21

* Radial distances for isopleths/thresholds that envelope the FPSO and OSV were reported from the mid-point between the FPSO and the OSV modelled sites. Otherwise radial distances were reported from the FPSO modelled location.
A dash indicates the threshold was not reached within the limits of the modelling resolution (20 m).

Table 46. *Vessels, marine mammal behavioural response thresholds, SPL*: Summary of maximum distances.

Threshold	Distance R_{max} (km)			
	FPSO on DP	FPSO without DP	OSV	Offtake operations*
Marine mammal behaviour, SPL: 120 dB re 1 µPa (NOAA 2019)	10.4	1.49	4.57	11.0

* Radial distances for isopleths/thresholds that envelope the FPSO and OSV were reported from the mid-point between the FPSO and the OSV modelled sites. Otherwise radial distances were reported from the FPSO modelled location.

5.4.3. Sea Turtles

- Finneran et al. (2017) criteria for sea turtle Permanent Threshold Shift (PTS) and Temporary Threshold Shift (TTS): TTS is not predicted to occur for the FPSO without DP within the modelling resolution of 20 m, and only at distances of up to 50 m for the FPSO under DP and offtake operations. PTS is not predicted to occur.

5.4.4. Fish

- Popper et al. (2014): Sound produced by the vessel operations could cause physiological effects, and recoverable injury, to some fish species, but only if the animals are in very close proximity to the sound sources–within a planar distance of 30 m, for 48 h. Temporary impairment due to TTS could occur at similar short distances if fish remain at the same location within the sound field for a duration exceeding 12 h.

6. Glossary

1/3-octave
One third of an octave. Note: A one-third octave is approximately equal to one decidecade (1/3 oct ≈ 1.003 ddec; ISO 2017).

1/3-octave-band
Frequency band whose bandwidth is one one-third octave. Note: The bandwidth of a one-third octave-band increases with increasing centre frequency.

absorption
The reduction of acoustic pressure amplitude due to acoustic particle motion energy converting to heat in the propagation medium.

acoustic impedance
The ratio of the sound pressure in a medium to the rate of alternating flow of the medium through a specified surface due to the sound wave.

ambient noise
All-encompassing sound at a given place, usually a composite of sound from many sources near and far (ANSI S1.1-1994 R2004), e.g., shipping vessels, seismic activity, precipitation, sea ice movement, wave action, and biological activity.

attenuation
The gradual loss of acoustic energy from absorption and scattering as sound propagates through a medium.

Auditory frequency weighting (auditory weighting function, frequency-weighting function)
The process of band-pass filtering sounds to reduce the importance of inaudible or less-audible frequencies for individual species or groups of species of aquatic mammals (ISO 2017). One example is M-weighting introduced by Southall et al. (2007) to describe "Generalized frequency weightings for various functional hearing groups of marine mammals, allowing for their functional bandwidths and appropriate in characterising auditory effects of strong sounds".

azimuth
A horizontal angle relative to a reference direction, which is often magnetic north or the direction of travel. In navigation it is also called bearing.

bandwidth
The range of frequencies over which a sound occurs. Broadband refers to a source that produces sound over a broad range of frequencies (e.g., seismic airguns, vessels) whereas narrowband sources produce sounds over a narrow frequency range (e.g., sonar) (ANSI/ASA S1.13-2005 R2010).

bar
Unit of pressure equal to 100 kPa, which is approximately equal to the atmospheric pressure on Earth at sea level. 1 bar is equal to 10^5 Pa or 10^{11} µPa.

broadband sound level
The total sound pressure level measured over a specified frequency range. If the frequency range is unspecified, it refers to the entire measured frequency range.

broadside direction
Perpendicular to the travel direction of a source. Compare with endfire direction.

cavitation
A rapid formation and collapse of vapor cavities (i.e., bubbles or voids) in water, most often caused by a rapid change in pressure. Fast-spinning vessel propellers typically cause cavitation, which creates a lot of noise.

cetacean
Any animal in the order Cetacea. These are aquatic, mostly marine mammals and include whales, dolphins, and porpoises.

compressional wave
A mechanical vibration wave in which the direction of particle motion is parallel to the direction of propagation. Also called primary wave or P-wave.

continuous sound
A sound whose sound pressure level remains above ambient sound during the observation period (ANSI/ASA S1.13-2005 R2010). A sound that gradually varies in intensity with time, for example, sound from a marine vessel.

decade
Logarithmic frequency interval whose upper bound is ten times larger than its lower bound (ISO 2006).

decidecade
One tenth of a decade (ISO 2017). Note: An alternative name for decidecade (symbol ddec) is “one-tenth decade”. A decidecade is approximately equal to one third of an octave (1 ddec ≈ 0.3322 oct) and for this reason is sometimes referred to as a “one-third octave”.

decidecade band
Frequency band whose bandwidth is one decidecade. Note: The bandwidth of a decidecade band increases with increasing centre frequency.

decibel (dB)
One-tenth of a bel. Unit of level when the base of the logarithm is the tenth root of ten, and the quantities concerned are proportional to power (ANSI S1.1-1994 R2004).

endfire direction
Parallel to the travel direction of a source. See also broadside direction.

ensonified
Exposed to sound.

far-field
The zone where, to an observer, sound originating from an array of sources (or a spatially distributed source) appears to radiate from a single point. The distance to the acoustic far-field increases with frequency.

fast-average sound pressure level
The time-averaged sound pressure levels calculated over the duration of a pulse (e.g., 90%-energy time window), using the leaky time integrator from Plomp and Bouman (1959) and a time constant of 125 ms. Typically used only for pulsed sounds.

fast Fourier transform (FFT)
A computationally efficiently algorithm for computing the discrete Fourier transform.

frequency
The rate of oscillation of a periodic function measured in cycles-per-unit-time. The reciprocal of the period. Unit: hertz (Hz). Symbol: *f*. 1 Hz is equal to 1 cycle per second.

hearing group
Groups of marine mammal species with similar hearing ranges. Commonly defined functional hearing groups include low-, high-, and very-high-frequency cetaceans, pinnipeds in water, and pinnipeds in air.

geoacoustic
Relating to the acoustic properties of the seabed.

hearing threshold
The sound pressure level for any frequency of the hearing group that is barely audible for a given individual in the absence of significant background noise during a specific percentage of experimental trials.

hertz (Hz)
A unit of frequency defined as one cycle per second.

high-frequency (HF) cetacean
The functional cetacean hearing group that represents those odontocetes (toothed whales) specialised for high-frequency hearing. Mid-frequency cetaceans from NMFS (2018) are classified as high-frequency cetaceans in Southall et al. (2019).

intermittent sound
A level of sound that abruptly drops to the background noise level several times during the observation period.

impulsive sound
Sound that is typically brief and intermittent with rapid (within a few seconds) rise time and decay back to ambient levels (NOAA 2013, ANSI S12.7-1986 R2006). For example, seismic airguns and impact pile driving.

low-frequency (LF) cetacean
The functional cetacean hearing group that represents mysticetes (baleen whales) specialised for hearing low frequencies.

masking
Obscuring of sounds of interest by sounds at similar frequencies.

median
The 50th percentile of a statistical distribution.

Monte Carlo simulation
The method of investigating the distribution of a non-linear multi-variate function by random sampling of all of its input variable distributions.

mysticete
Mysticeti, a suborder of cetaceans, use their baleen plates, rather than teeth, to filter food from water. They are not known to echolocate, but they use sound for communication. Members of this group include rorquals (Balaenopteridae), right whales (Balaenidae), and grey whales (*Eschrichtius robustus*).

non-impulsive sound
Sound that is broadband, narrowband or tonal, brief or prolonged, continuous or intermittent, and typically does not have a high peak pressure with rapid rise time (typically only small fluctuations in decibel level) that impulsive signals have (ANSI/ASA S3.20-1995 R2008). For example, marine vessels, aircraft, machinery, construction, and vibratory pile driving (NIOSH 1998, NOAA 2015).

octave
The interval between a sound and another sound with double or half the frequency. For example, one octave above 200 Hz is 400 Hz, and one octave below 200 Hz is 100 Hz.

odontocete
The presence of teeth, rather than baleen, characterizes these whales. Members of the Odontoceti are a suborder of cetaceans, a group comprised of whales, dolphins, and porpoises. The skulls of

toothed whales are mostly asymmetric, an adaptation for their echolocation. This group includes sperm whales, killer whales, belugas, narwhals, dolphins, and porpoises.

parabolic equation method
A computationally efficient solution to the acoustic wave equation that is used to model transmission loss. The parabolic equation approximation omits effects of back-scattered sound, simplifying the computation of transmission loss. The effect of back-scattered sound is negligible for most ocean-acoustic propagation problems.

peak pressure level (PK)
The maximum instantaneous sound pressure level, in a stated frequency band, within a stated period. Also called zero-to-peak pressure level. Unit: decibel (dB).

peak-to-peak pressure level (PK-PK)
The difference between the maximum and minimum instantaneous pressure levels. Unit: decibel (dB).

percentile level, exceedance
The sound level exceeded *n*% of the time during a measurement.

permanent threshold shift (PTS)
A permanent loss of hearing sensitivity caused by excessive noise exposure. PTS is considered auditory injury.

pinniped
A common term used to describe all three groups that form the superfamily Pinnipedia: phocids (true seals or earless seals), otariids (eared seals or fur seals and sea lions), and walrus.

point source
A source that radiates sound as if from a single point (ANSI S1.1-1994 R2004).

pressure, acoustic
The deviation from the ambient hydrostatic pressure caused by a sound wave. Also called overpressure. Unit: pascal (Pa). Symbol: *p*.

pressure, hydrostatic
The pressure at any given depth in a static liquid that is the result of the weight of the liquid acting on a unit area at that depth, plus any pressure acting on the surface of the liquid. Unit: pascal (Pa).

received level (RL)
The sound level measured (or that would be measured) at a defined location.

rms
root-mean-square.

signature
Pressure signal generated by a source.

sound
A time-varying pressure disturbance generated by mechanical vibration waves travelling through a fluid medium such as air or water.

sound exposure
Time integral of squared, instantaneous frequency-weighted sound pressure over a stated time interval or event. Unit: pascal-squared second ($Pa^2 \cdot s$) (ANSI S1.1-1994 R2004).

sound exposure level (SEL)
A cumulative measure related to the sound energy in one or more pulses. Unit: dB re 1 µPa²·s. SEL is expressed over the summation period (e.g., per-pulse SEL [for airguns], single-strike SEL [for pile drivers], 24-hour SEL).

sound exposure spectral density
Distribution as a function of frequency of the time-integrated squared sound pressure per unit bandwidth of a sound having a continuous spectrum (ANSI S1.1-1994 R2004). Unit: µPa²·s/Hz.

sound field
Region containing sound waves (ANSI S1.1-1994 R2004).

sound intensity
Sound energy flowing through a unit area perpendicular to the direction of propagation per unit time.

sound pressure level (SPL)
The decibel ratio of the time-mean-square sound pressure, in a stated frequency band, to the square of the reference sound pressure (ANSI S1.1-1994 R2004).

For sound in water, the reference sound pressure is one micropascal (p_0 = 1 µPa) and the unit for SPL is dB re 1 µPa²:

$$L_p = 10\log_{10}(p^2/p_0^2) = 20\log_{10}(p/p_0)$$

Unless otherwise stated, SPL refers to the root-mean-square (rms) pressure level. See also 90% sound pressure level and fast-average sound pressure level. Non-rectangular time window functions may be applied during calculation of the rms value, in which case the SPL unit should identify the window type.

sound speed profile
The speed of sound in the water column as a function of depth below the water surface.

source level (SL)
The sound level measured in the far-field and scaled back to a standard reference distance of 1 metre from the acoustic centre of the source. Unit: dB re 1 µPa·m (pressure level) or dB re 1 µPa²·s·m (exposure level).

spectrogram
A visual representation of acoustic amplitude compared with time and frequency.

spectrum
An acoustic signal represented in terms of its power, energy, mean-square sound pressure, or sound exposure distribution with frequency.

temporary threshold shift (TTS)
Temporary loss of hearing sensitivity caused by excessive noise exposure.

transmission loss (TL)
The decibel reduction in sound level between two stated points that results from sound spreading away from an acoustic source subject to the influence of the surrounding environment. Also referred to as propagation loss.

very-high-frequency (HF) cetacean
The functional cetacean hearing group that represents those odontocetes (toothed whales) specialised for very-high-frequency hearing. High-frequency cetaceans from NMFS (2018) are classified as very-high-frequency cetaceans in Southall et al. (2019).

wavelength
Distance over which a wave completes one cycle of oscillation. Unit: metre (m). Symbol: λ.

Appendix A. Acoustic Metrics

A.1. Pressure Related Acoustic Metrics

Underwater sound pressure amplitude is measured in decibels (dB) relative to a fixed reference pressure of p_0 = 1 μPa. Because the perceived loudness of sound, especially impulsive noise such as from seismic airguns, pile driving, and sonar, is not generally proportional to the instantaneous acoustic pressure, several sound level metrics are commonly used to evaluate noise and its effects on marine life. We provide specific definitions of relevant metrics used in the accompanying report. Where possible we follow the ANSI and ISO standard definitions and symbols for sound metrics, but these standards are not always consistent.

The zero-to-peak sound pressure level (PK; L_{pk}; $L_{p,pk}$; dB re 1 µPa), is the maximum instantaneous sound pressure level in a stated frequency band attained by an acoustic pressure signal, $p(t)$:

$$L_{p,pk} = 20\log_{10}\left[\frac{\max(|p(t)|)}{p_0}\right] \quad \text{(A-1)}$$

PK is often included as a criterion for assessing whether a sound is potentially injurious; however, because it does not account for the duration of a noise event, it is generally a poor indicator of perceived loudness.

The peak-to-peak sound pressure level (PK-PK; $L_{pk\text{-}pk}$; $L_{p,pk\text{-}pk}$; dB re 1 µPa) is the difference between the maximum and minimum instantaneous sound pressure levels in a stated frequency band attained by an impulsive sound, $p(t)$:

$$L_{p,pk-pk} = 10\log_{10}\left\{\frac{[\max(p(t)) - \min(p(t))]^2}{p_0^2}\right\} \quad \text{(A-2)}$$

The sound pressure level (SPL; L_p; dB re 1 µPa) is the rms pressure level in a stated frequency band over a specified time window (T, s) containing the acoustic event of interest. It is important to note that SPL always refers to a rms pressure level and therefore not instantaneous pressure:

$$L_p = 10\log_{10}\left(\frac{1}{T}\int_T p^2(t)dt \Big/ p_0^2\right) \quad \text{(A-3)}$$

The SPL represents a nominal effective continuous sound over the duration of an acoustic event, such as the emission of one acoustic pulse, a marine mammal vocalisation, the passage of a vessel, or over a fixed duration. Because the window length, T, is the divisor, events with similar sound exposure level (SEL) but more spread out in time have a lower SPL. A fixed window length of 0.125 s (critical duration defined by Tougaard et al. (2015)) is used in this study for impulsive sounds.

The sound exposure level (SEL; L_E; $L_{E,p}$; dB re 1 µPa^2·s) is a measure related to the acoustic energy contained in one or more acoustic events (N). The SEL for a single event is computed from the time-integral of the squared pressure over the full event duration (T):

$$L_E = 10\log_{10}\left(\int_T p^2(t)dt \Big/ T_0 p_0^2\right) \quad \text{(A-4)}$$

where T_0 is a reference time interval of 1 s. The SEL continues to increase with time when non-zero pressure signals are present. It therefore can be construed as a dose-type measurement, so the integration time used must be carefully considered in terms of relevance for impact to the exposed recipients.

SEL can be calculated over periods with multiple acoustic events or over a fixed duration. For a fixed duration, the square pressure is integrated over the duration of interest. For multiple events, SEL can be computed by summing (in linear units) SEL of the *N* individual events:

$$L_{E,N} = 10\log_{10}\left(\sum_{i=1}^{N} 10^{\frac{L_{E,i}}{10}}\right). \tag{A-5}$$

If applied, the frequency weighting of an acoustic event should be specified, as in the case of weighted SEL (e.g., $L_{E,LFC,24h}$; Appendix A.3). The use of fast, slow, or impulse exponential-time-averaging or other time-related characteristics should else be specified.

A.2. Marine Mammal Impact Criteria

It has been long recognised that marine mammals can be adversely affected by underwater anthropogenic noise. For example, Payne and Webb (1971) suggested that communication distances of fin whales are reduced by shipping sounds. Subsequently, similar concerns arose regarding effects of other underwater noise sources and the possibility that impulsive sources–primarily airguns used in seismic surveys–could cause auditory injury. This led to a series of workshops held in the late 1990s, conducted to address acoustic mitigation requirements for seismic surveys and other underwater noise sources (NMFS 1998, ONR 1998, Nedwell and Turnpenny 1998, HESS 1999, Ellison and Stein 1999). In the years since these early workshops, a variety of thresholds have been proposed for both injury and disturbance. The following sections summarize the recent development of thresholds; however, this field remains an active research topic.

A.2.1. Auditory Impairment

There are two categories of auditory threshold shifts (also termed Noise Induced Threshold Shift, NITS): Permanent Threshold Shift (PTS), a physical injury to an animal's hearing system; and Temporary Threshold Shift (TTS), a temporary reduction in an animal's hearing sensitivity as the result of physiological and mechanical processes in the inner ear. While PTS undoubtedly constitutes an injury, TTS (as a temporary effect) was not considered in the same way. However, recent research clearly indicates that already moderate levels (<12 dB) of TTS produced an accelerated hearing loss (PTS) resulting from progressive neural degeneration with age (Kujawa and Liberman 2006, 2009, Maison et al. 2013, Kujawa and Liberman 2015).

The most recent criteria for assessing possible effects of impulsive sounds (such as pile driving or seismic impulses) noise and non-impulsive sound (such as vessel noise) on marine mammals, Southall et al. (2019), was applied in this study.

A.2.2. Behavioural response

Numerous studies on marine mammal behavioural responses to sound exposure have not resulted in consensus in the scientific community regarding the appropriate metric for assessing behavioural reactions. However, it is recognised that the context in which the sound is received affects the nature and extent of responses to a stimulus (Southall et al. 2007, Ellison and Frankel 2012, Southall et al. 2016).

For non-impulsive noise, NMFS currently uses step function (all-or-none) threshold of 120 dB re 1 µPa SPL (unweighted) to assess and regulate noise-induced behavioural impacts for marine mammals (NOAA 2019). The 120 dB re 1 µPa threshold is associated with continuous sources and was derived based on studies examining behavioural responses to drilling and dredging (NOAA 2018), referring to Malme et al. (1983), Malme et al. (1984), and Malme et al. (1986), which were considered in Southall et al. (2007). Malme et al. (1986) found that playback of drillship noise did not produce clear evidence of disturbance or avoidance for levels below 110 dB re 1 µPa (SPL), possible avoidance occurred for exposure levels approaching 119 dB re 1 µPa. Malme et al. (1984) determined that measurable reactions usually consisted of rather subtle short-term changes in speed and/or heading of the whale(s) under observation. It has been shown that both received level and proximity of the sound source is a contributing factor in eliciting behavioural reactions in humpback whales (Dunlop et al. 2017, Dunlop et al. 2018).

For impulsive noise, NMFS currently uses step function thresholds of 160 dB re 1 µPa SPL (unweighted) to assess and regulate noise-induced behavioural impacts for marine mammals (NOAA 2018, NOAA 2019). The threshold for impulsive sound is derived from the High-Energy Seismic Survey (HESS) panel (HESS 1999) report that, in turn, is based on the responses of migrating mysticete whales to airgun sounds (Malme et al. 1984). The HESS team recognised that behavioural responses to sound may occur at lower levels, but significant responses were only likely to occur above a SPL of 140 dB re 1 µPa. Southall et al. (2007) found varying responses for most marine mammals between a SPL of 140 and 180 dB re 1 µPa, consistent with the HESS (1999) report, but lack of convergence in the data prevented them from suggesting explicit step functions.

A.3. Marine Mammal Frequency Weighting

The potential for noise to affect animals depends on how well the animals can hear it. Noises are less likely to disturb or injure an animal if they are at frequencies that the animal cannot hear well. An exception occurs when the sound pressure is so high that it can physically injure an animal by non-auditory means (i.e., barotrauma). For sound levels below such extremes, the importance of sound components at particular frequencies can be scaled by frequency weighting relevant to an animal's sensitivity to those frequencies (Nedwell and Turnpenny 1998, Nedwell et al. 2007).

A.3.1. Marine mammal frequency weighting functions

In 2015, a U.S. Navy technical report by Finneran (2015) recommended new auditory weighting functions. The overall shape of the auditory weighting functions is similar to human A-weighting functions, which follows the sensitivity of the human ear at low sound levels. The new frequency-weighting function is expressed as:

$$G(f) = K + 10\log_{10}\left[\left(\frac{(f/f_{lo})^{2a}}{\left[1+(f/f_{lo})^2\right]^a\left[1+(f/f_{hi})^2\right]^b}\right)\right] \quad \text{(A-6)}$$

Finneran (2015) proposed five functional hearing groups for marine mammals in water: low-, mid-, and high-frequency cetaceans, phocid pinnipeds, and otariid pinnipeds. The parameters for these frequency-weighting functions were further modified the following year (Finneran 2016) and were adopted in NOAA's technical guidance that assesses noise impacts on marine mammals (NMFS 2016, NMFS 2018). Mid-frequency cetaceans from NMFS (2018) are classified as high-frequency cetaceans in Southall et al. (2019), and high-frequency cetaceans from NMFS (2018) are classified as very-high-frequency cetaceans, but the weighting functions remain the same. Table A-1 lists the frequency-weighting parameters for each hearing group; Figure A-1 shows the resulting frequency-weighting curves.

Table A-1. Parameters for the auditory weighting functions used in this project as recommended by Southall et al. (2019).

Hearing group	a	b	f_{lo} (Hz)	f_{hi} (kHz)	K (dB)
Low-frequency cetaceans (baleen whales)	1.0	2	200	19,000	0.13
High-frequency cetaceans (dolphins, plus toothed, beaked, and bottlenose whales)	1.6	2	8,800	110,000	1.20
Very-high-frequency cetaceans (true porpoises, *Kogia*, river dolphins, cephalorhynchid, *Lagenorhynchus cruciger* and *L. australis*)	1.8	2	12,000	140,000	1.36

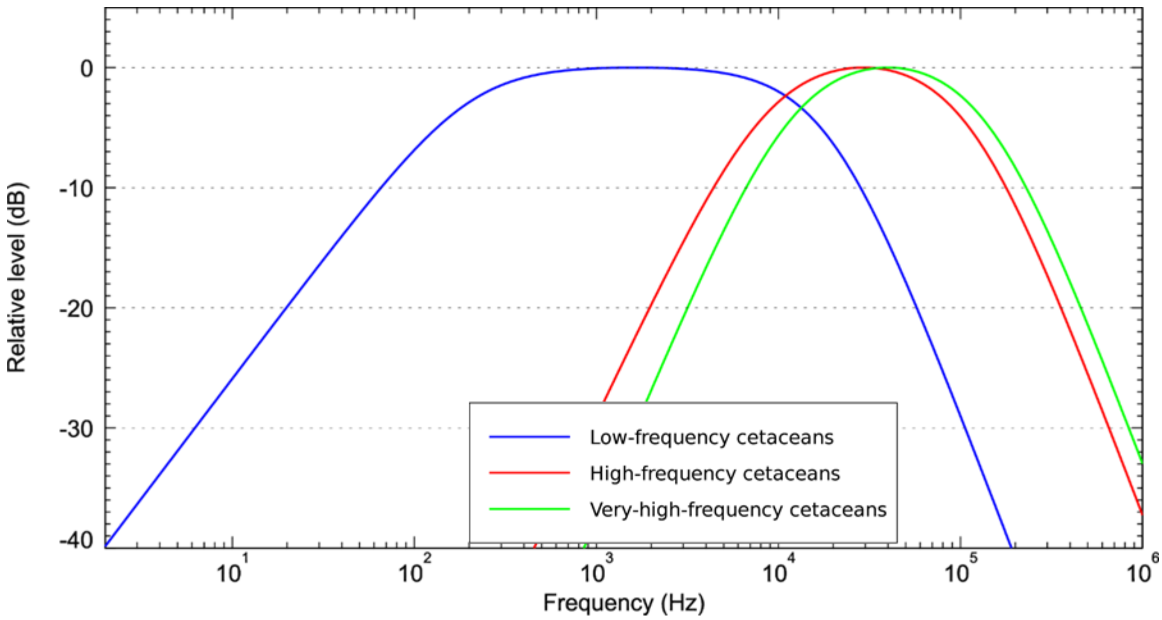

Figure A-1. Auditory weighting functions for functional marine mammal hearing groups as recommended by Southall et al. (2019).

Appendix B. Pile Driving Acoustic Source Model

A physical model of pile vibration and near-field sound radiation is used to calculate source levels of piles. The physical model employed in this study computes the underwater vibration and sound radiation of a pile by solving the theoretical equations of motion for axial and radial vibrations of a cylindrical shell. These equations of motion are solved subject to boundary conditions, which describe the forcing function of the hammer at the top of the pile and the soil resistance at the base of the pile (Figure B-1). Damping of the pile vibration due to radiation loading is computed for Mach waves emanating from the pile wall. The equations of motion are discretised using the finite difference (FD) method and are solved on a discrete time and depth mesh.

To model the sound emissions from the piles, the force of the pile driving hammers also had to be modelled. The force at the top of each pile was computed using the GRLWEAP 2010 wave equation model (GRLWEAP, Pile Dynamics 2010), which includes a large database of simulated hammers–both impact and vibratory–based on the manufacturer's specifications. The forcing functions from GRLWEAP were used as inputs to the FD model to compute the resulting pile vibrations.

The sound radiating from the pile itself is simulated using a vertical VSP array of discrete point sources. The point sources are centred on the pile axis. Their amplitudes are derived using an inverse technique, such that their collective particle velocity–calculated using a near-field wave-number integration model–matches the particle velocity in the water at the pile wall. The sound field propagating away from the vertical source VSP array is then calculated using a time-domain acoustic propagation model (FWRAM, Appendix E.2). MacGillivray (2014) describes the theory behind the physical model in more detail. The accuracy of JASCO's pile driving model has been verified by comparing its output against benchmark scenarios (Lippert et al. 2016) and detailed measurement programs (Austin et al. 2016, Denes et al. 2016, MacGillivray 2018).

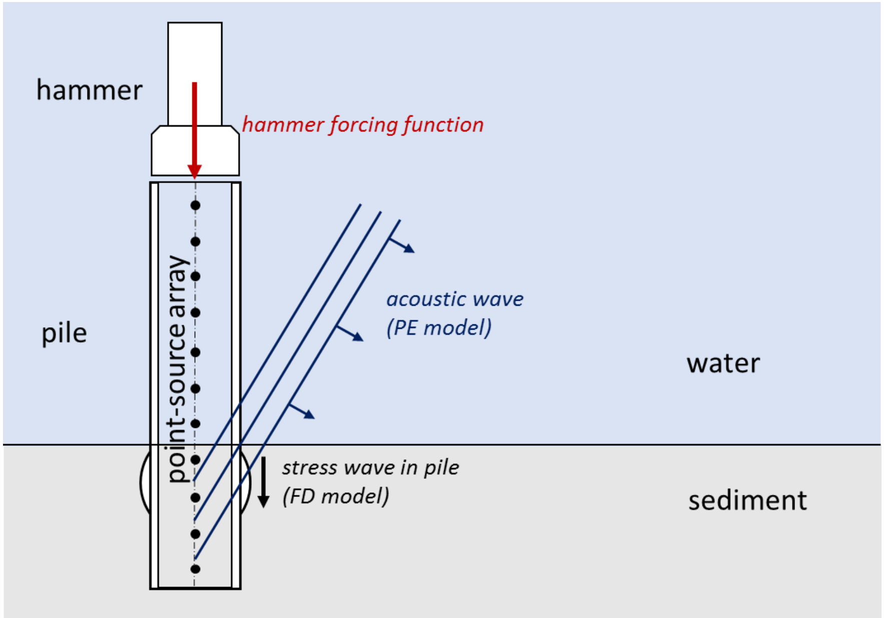

Figure B-1. Physical model geometry for impact driving of a cylindrical pile (vertical cross-section). The hammer forcing function is used with the finite difference (FD) model to compute the stress wave vibration in the pile. A vertical VSP array of point sources is used with the parabolic equation (PE) model to compute the acoustic waves that the pile wall radiates.

Appendix C. VSP Source

C.1. Airgun Array Source Model

The source levels and directivity of the seismic source were predicted with JASCO's Airgun Array Source Model (AASM). AASM includes low- and high-frequency modules for predicting different components of the seismic source spectrum. The low-frequency module is based on the physics of oscillation and radiation of airgun bubbles, as originally described by Ziolkowski (1970), that solves the set of parallel differential equations that govern bubble oscillations. Physical effects accounted for in the simulation include pressure interactions between airguns, port throttling, bubble damping, and generator-injector (GI) gun behaviour discussed by Dragoset (1984), Laws et al. (1990), and Landrø (1992). A global optimisation algorithm tunes free parameters in the model to a large library of airgun source signatures.

While airgun signatures are highly repeatable at the low frequencies, which are used for seismic imaging, their sound emissions have a large random component at higher frequencies that cannot be predicted using a deterministic model. Therefore, AASM uses a stochastic simulation to predict the high-frequency (800−25,000 Hz) sound emissions of individual airguns, using a data-driven multiple-regression model. The multiple-regression model is based on a statistical analysis of a large collection of high quality seismic source signature data recently obtained from the Joint Industry Program (JIP) on Sound and Marine Life (Mattsson and Jenkerson 2008). The stochastic model uses a Monte-Carlo simulation to simulate the random component of the high-frequency spectrum of each airgun in an array. The mean high-frequency spectra from the stochastic model augment the low-frequency signatures from the physical model, allowing AASM to predict airgun source levels at frequencies up to 25,000 Hz.

AASM produces a set of "notional" signatures for each array element based on:

- Array layout
- Volume, operating depth, and firing pressure of each airgun
- Interactions between different airguns in the array

These notional signatures are the pressure waveforms of the individual airguns at a standard reference distance of 1 m; they account for the interactions with the other airguns in the array. The signatures are summed with the appropriate phase delays to obtain the far-field source signature of the entire array in all directions. This far-field array signature is filtered into 1/3-octave-bands to compute the source levels of the array as a function of frequency band and azimuthal angle in the horizontal plane (at the source depth), after which it is considered a directional point source in the far field.

A seismic array consists of many sources and the point source assumption is invalid in the near field where the array elements add incoherently. The maximum extent of the near field of an array (R_{nf}) is:

$$R_{nf} < \frac{l^2}{4\lambda} \quad \text{(C-1)}$$

where λ is the sound wavelength and l is the longest dimension of the array (Lurton 2002, §5.2.4). For example, a seismic source length of l = 21 m yields a near-field range of 147 m at 2 kHz and 7 m at 100 Hz. Beyond this R_{nf} range, the array is assumed to radiate like a directional point source and is treated as such for propagation modelling.

The interactions between individual elements of the array create directionality in the overall acoustic emission. Generally, this directionality is prominent mainly at frequencies in the mid-range between tens of hertz to several hundred hertz. At lower frequencies, with acoustic wavelengths much larger than the inter-airgun separation distances, the directionality is small. At higher frequencies, the pattern of lobes is too finely spaced to be resolved and the effective directivity is less.

C.2. VSP Source Parameters

The layout of the seismic source is provided in Figure F-1. Details of the airgun parameters are provided in Table C-1. In the context of this source geometry the broadside direction is perpendicular to the sagittal plane of the array and the endfire direction is parallel to the sagittal plane of the array.

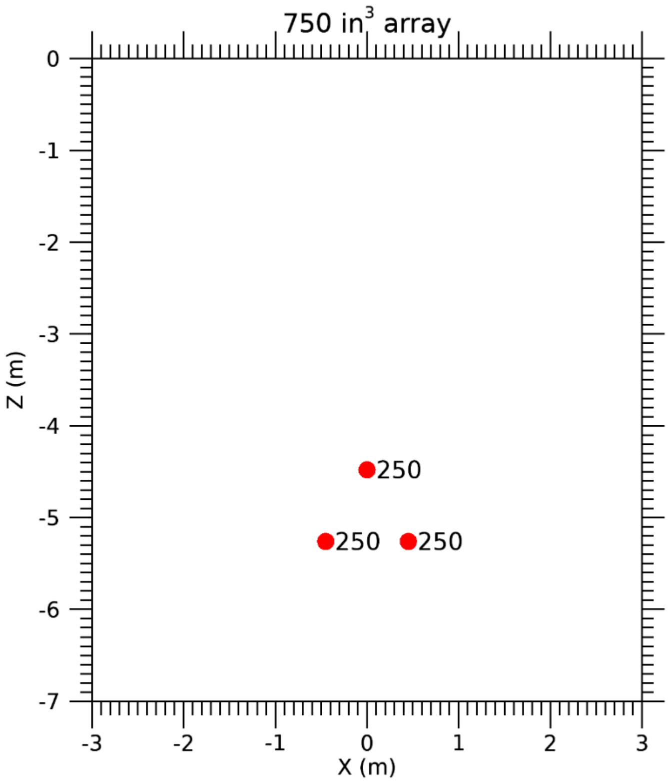

Figure C-1. Layout of the modelled 750 in^3 seismic source array. Operational depth is 5 m. The labels indicate the firing volume (in cubic inches) for each airgun. Also see Table C-1.

Table C-1. Layout of the modelled 750 in^3 seismic source array. Operational depth is 5 m. Firing pressure for all guns is 2000 psi. Also see Figure C-1.

Gun	x (m)	y (m)	z (m)	Volume (in^3)
1	0.0	0.0	4.48	250
2	0.0	0.45	5.26	250
3	0.0	-0.45	5.26	250

C.3. Array Source Levels and Directivity

Figure C-2 shows the broadside (perpendicular to the sagittal plane), endfire (parallel to the sagittal plane), and vertical overpressure signature and corresponding power spectrum levels for the 750 in^3 array (Appendix C.2). Horizontal 1/3-octave-band source levels shown as a function of band centre frequency and azimuth (Figure C-3) indicate that this array is mainly isotropic.

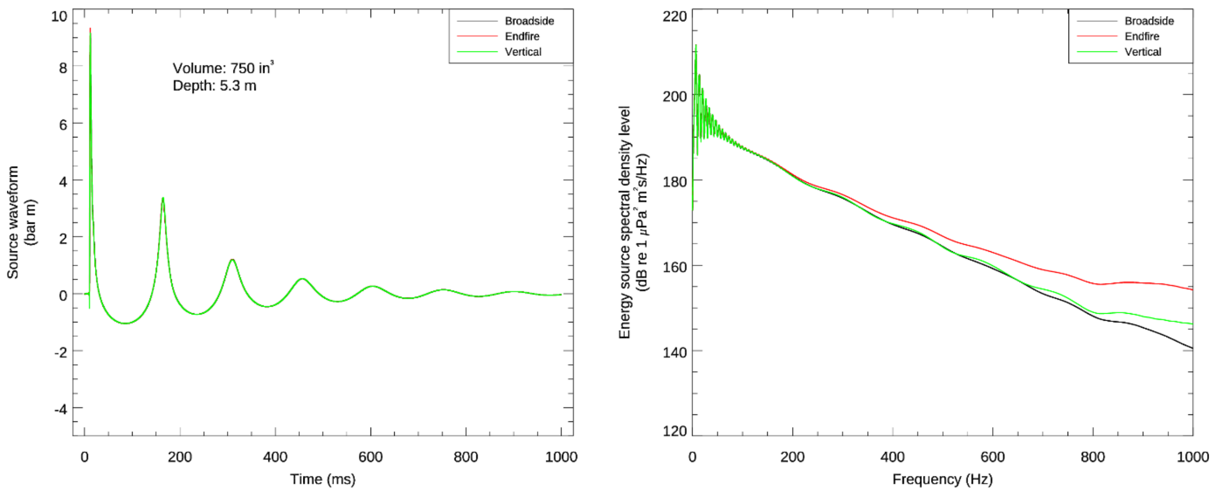

Figure C-2. Predicted source level details for the 750 in^3 array at a 6 m operational depth.(Left) the overpressure signature and (right) the power spectrum for in-plane horizontal (broadside), perpendicular (endfire), and vertical directions.

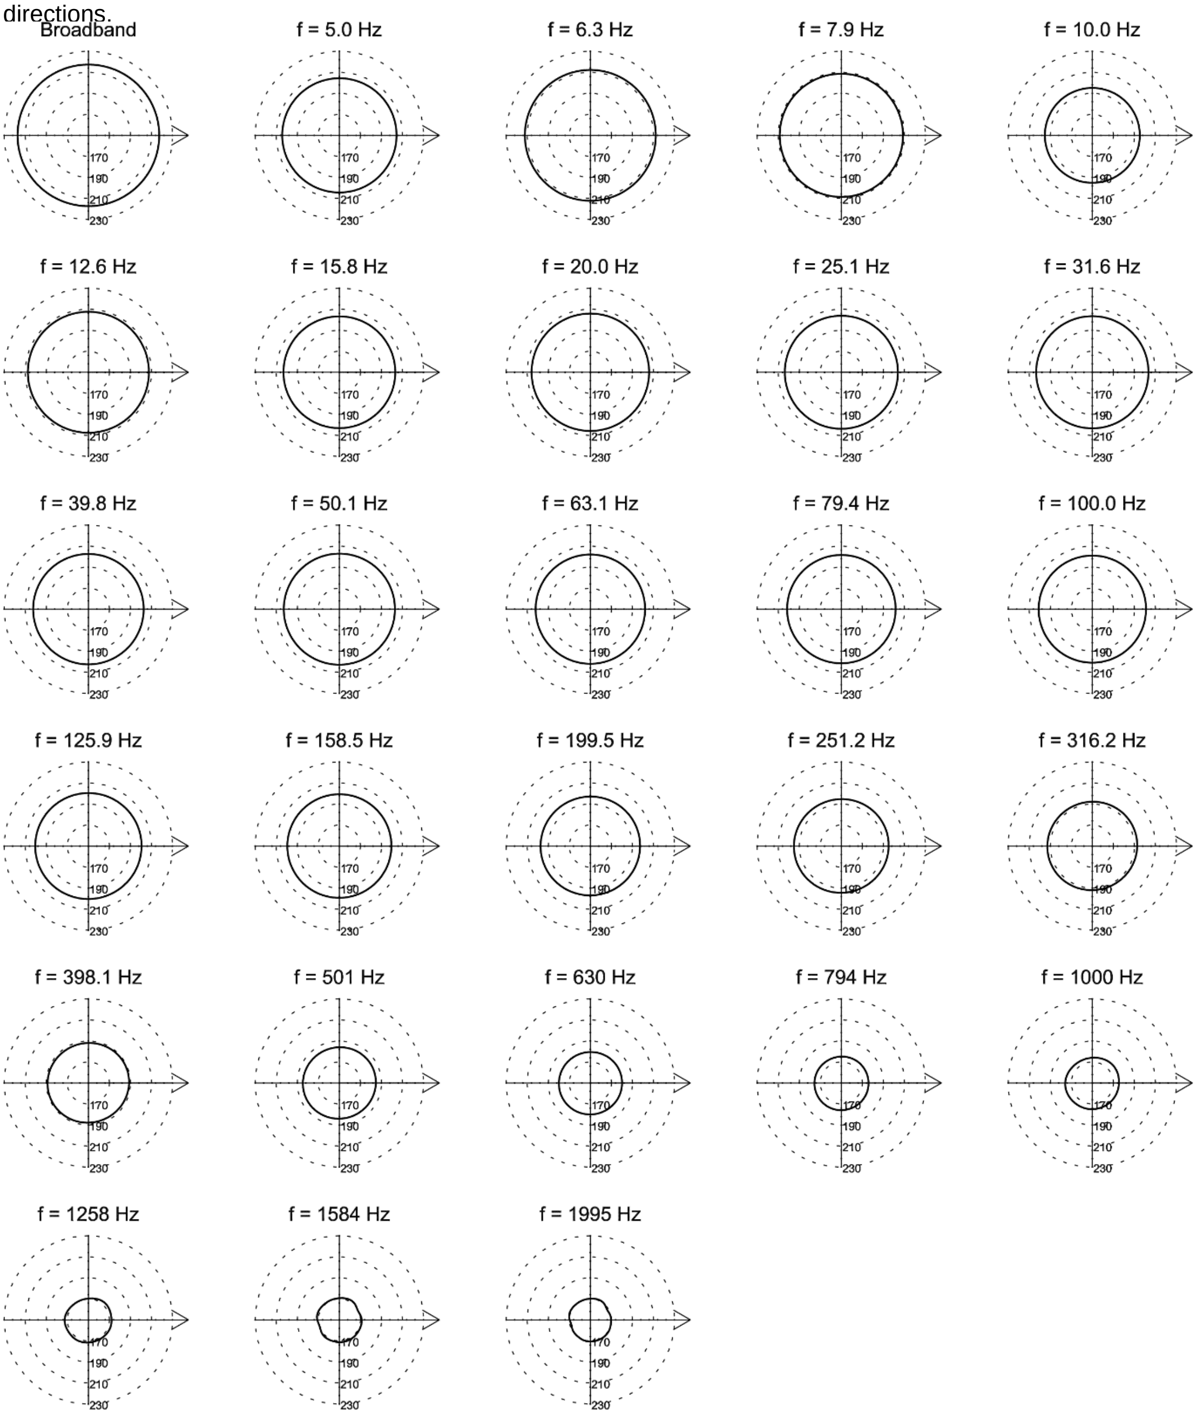

Figure C-3. Directionality of the predicted horizontal source levels for the 750 in^3 seismic source array, 10 Hz to 2 kHz. Source levels (in dB re 1 $\mu Pa^2 \cdot s\ m^2$) are shown as a function of azimuth for the centre frequencies of the 1/3-octave-bands modelled; frequencies are shown above the plots. The endfire axis is to the right. Operational depth is 5 m.

Appendix D. Thruster Source Level Estimation

Underwater sound that radiates from vessels is produced mainly by propeller and thruster cavitation, with a smaller fraction of sound produced by sound transmitted through the hull, such as by engines, gearing, and other mechanical systems. Sound levels tend to be the highest when thrusters are used to position the vessel and when the vessel is transiting at high speeds. A vessel's sound signature depends on the vessel's size, power output, propulsion system, and the design characteristics of the given system (e.g., blade shape and size). A vessel produces broadband acoustic energy with most of the energy emitted below a few kilohertz. Sound from onboard machinery, particularly sound below 200 Hz, dominates the sound spectrum before cavitation begins–normally around 8–12 knots on many commercial vessels (Spence et al. 2007). Under higher speeds and higher propulsion system load, the acoustic output from the cavitation processes on the propeller blades dominates other sources of sound on the vessel such as machinery or hull vibration (Leggat et al. 1981).

A vessel equipped with propellers/thrusters has two primary sources of sound that propagate from the unit: the machinery and the propellers. For thrusters operating in the heavily loaded conditions, the acoustic energy generated by the cavitation processes on the propeller blades dominates (Leggat et al. 1981). The sound power from the propellers is proportional to the number of blades, the propeller diameter, and the propeller tip speed.

Based on an analysis of acoustic data, Ross (1976) provided the following formula for the sound levels from a vessel's propeller, operating in calm, open ocean conditions:

$$L_{100} = 155 + 60\log(u/25) + 10\log(B/4)\,, \tag{D-1}$$

where L_{100} is the spectrum level at 100 Hz, u is the propeller tip speed (m/s), and B is the number of propeller blades. Equation D-1 gives the total energy produced by the propeller cavitation at frequencies between 100 Hz and 10 kHz. This equation is valid for a propeller tip speed between 15 and 50 m/s. The spectrum is assumed to be flat below 100 Hz. Its level is assumed to fall off at a rate of −6 dB per octave above 100 Hz (Figure D-1).

Another method of predicting the source level of a propeller was suggested by Brown (1977). For propellers operating in heavily loaded conditions, the formula for the sound spectrum level is:

$$\mathrm{SL}_B = 163 + 40\log D + 30\log N + 10\log B + 20\log f + 10\log(A_c/A_D)\,, \tag{D-2}$$

where D is the propeller diameter (m), N is the propeller revolution rate per second, B is the number of blades, A_C is the area of the blades covered by cavitation, and A_D is the total propeller disc area. Similar to Ross's approach, the spectrum below 100 Hz is assumed to be flat. The tests with a naval propeller operating at off-design heavily loaded conditions showed that Equation D-2 should be used with a value of $(A_c/A_D) = 1$ (Leggat et al. 1981).

The combined source level for multiple thrusters operating together can be estimated using the formula:

$$\mathrm{SL}_{\mathrm{total}} = 10\log_{10}\sum_i 10^{\frac{SL_i}{10}}, \tag{D-3}$$

where $\mathrm{SL}_{1,\ldots,N}$ are the source levels of individual thrusters. If the vessel is equipped with the same type of thrusters, the combined source level can be estimated using the formula:

$$\mathrm{SL}_N = \mathrm{SL} + 10\log N \tag{D-4}$$

where N is the total number of thrusters of the same type.

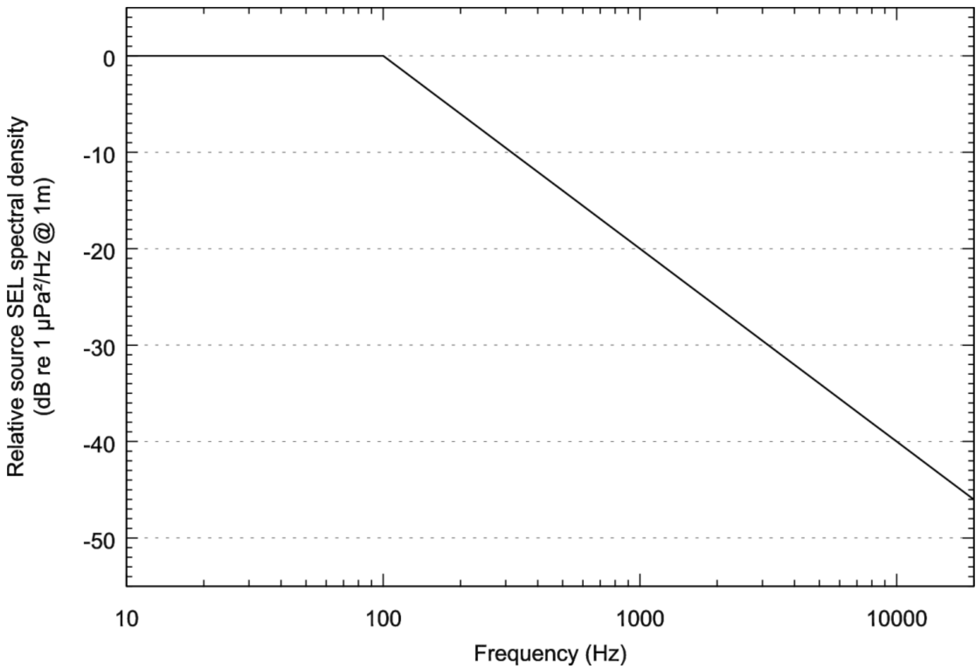

Figure D-1. Estimated sound spectrum from cavitating propeller (Leggat et al. 1981).

Appendix E. Sound Propagation Models

E.1. Transmission Loss

The propagation of sound through the environment was modelled by predicting the acoustic transmission loss–a measure, in decibels, of the decrease in sound level between a source and a receiver some distance away. Geometric spreading of acoustic waves is the predominant way by which transmission loss occurs. Transmission loss also happens when the sound is absorbed and scattered by the seawater, and absorbed scattered, and reflected at the water surface and within the seabed. Transmission loss depends on the acoustic properties of the ocean and seabed, its value changes with frequency.

If the acoustic source level (SL), expressed in dB re 1 µPa^{2}m^2, and transmission loss (TL), in units of dB, at a given frequency are known, then the received level (RL) at a receiver location can be calculated in dB re 1 µPa by:

$$\mathrm{RL} = \mathrm{SL} - \mathrm{TL} \tag{E-1}$$

E.2. Noise Propagation with FWRAM

For impulsive sounds from impact pile driving, time-domain representations of the pressure waves generated in the water are required to calculate SPL and peak pressure level. Furthermore, the pile must be represented as a distributed source to accurately characterise vertical directivity effects in the near-field zone. For this study, synthetic pressure waveforms were computed using JASCO's Full Waveform Range-dependent Acoustic Model (FWRAM). FWRAM computes acoustic propagation via a wide-angle parabolic equation solution to the acoustic wave equation (Collins 1993) based on a version of the U.S. Naval Research Laboratory's Range-dependent Acoustic Model (RAM), which has been modified to account for an elastic seabed (Zhang and Tindle 1995). The parabolic equation method has been extensively benchmarked and is widely employed in the underwater acoustics community (Collins et al. 1996). FWRAM accounts for the additional reflection loss at the seabed due to partial conversion of incident compressional waves to shear waves at the seabed and sub-bottom interfaces, and it includes wave attenuations in all layers. FWRAM incorporates the following site-specific environmental properties: a modelled area bathymetric grid, underwater sound speed as a function of depth, and a geoacoustic profile based on the overall stratified composition of the seafloor.

FWRAM computes pressure waveforms via Fourier synthesis of the modelled acoustic transfer function in closely spaced frequency bands. FWRAM employs the VSP array starter method to accurately model sound propagation from a spatially distributed source (MacGillivray and Chapman 2012).

Synthetic pressure waveforms from pile driving strikes were modelled and post-processed, after applying a travel time correction, to calculate standard SPL, SEL and PK metrics versus range and depth from the source.

E.3. MONM-BELLHOP

Long-range sound fields were computed using JASCO's Marine Operations Noise Model (MONM). Compared to VSTACK, MONM less accurately predicts steep-angle propagation for environments with higher shear speed but is well suited for effective longer-range estimation. This model computes sound propagation at frequencies of 10 Hz to 1.6 kHz via a wide-angle parabolic equation solution to the acoustic wave equation (Collins 1993) based on a version of the U.S. Naval Research Laboratory's Range-dependent Acoustic Model (RAM), which has been modified to account for a solid seabed (Zhang and Tindle 1995). MONM computes sound propagation at frequencies > 1.6 kHz via the BELLHOP Gaussian beam acoustic ray-trace model (Porter and Liu 1994).

The parabolic equation method has been extensively benchmarked and is widely employed in the underwater acoustics community (Collins et al. 1996). MONM accounts for the additional reflection loss at the seabed, which results from partial conversion of incident compressional waves to shear waves at the seabed and sub-bottom interfaces, and it includes wave attenuations in all layers. MONM incorporates the following site-specific environmental properties: a bathymetric grid of the modelled area, underwater sound speed as a function of depth, and a geoacoustic profile based on the overall stratified composition of the seafloor.

This version of MONM accounts for sound attenuation due to energy absorption through ion relaxation and viscosity of water in addition to acoustic attenuation due to reflection at the medium boundaries and internal layers (Fisher and Simmons 1977). The former type of sound attenuation is significant for frequencies higher than 5 kHz and cannot be neglected without noticeably affecting the model results.

MONM computes acoustic fields in three dimensions by modelling transmission loss within two-dimensional (2-D) vertical planes aligned along radials covering a 360° swath from the source, an approach commonly referred to as N×2-D. These vertical radial planes are separated by an angular step size of $\Delta\theta$, yielding N = 360°/$\Delta\theta$ number of planes (Figure E-1).

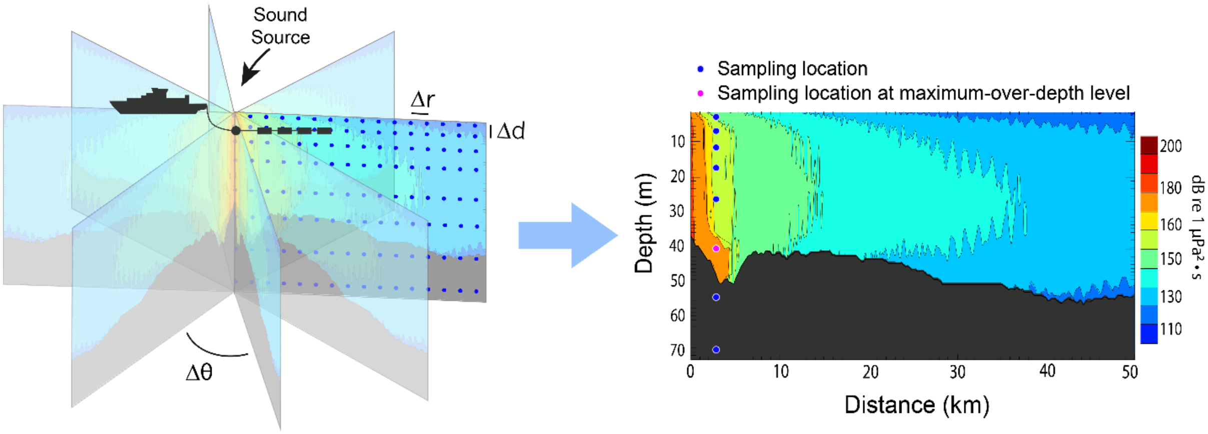

Figure E-1. The N×2-D and maximum-over-depth modelling approach used by MONM.

MONM treats frequency dependence by computing acoustic transmission loss at the centre frequencies of 1/3-octave-bands. Sufficiently many 1/3-octave-bands, starting at 10 Hz, are modelled to include most of the acoustic energy emitted by the source. At each centre frequency, the transmission loss is modelled within each of the N vertical planes as a function of depth and range from the source. The 1/3-octave-band received per-pulse SEL are computed by subtracting the band transmission loss values from the directional source level in that frequency band. Composite broadband received per-pulse SEL are then computed by summing the received 1/3-octave-band levels.

The received per-pulse (VSP source) or per-second vessel (FPSO, and OSV sources) SEL sound field within each vertical radial plane is sampled at various ranges from the source, generally with a fixed radial step size. At each sampling range along the surface, the sound field is sampled at various depths, with the step size between samples increasing with depth below the surface. The step sizes are chosen to provide increased coverage near the depth of the source and at depths of interest in terms of the sound speed profile. For areas with deep water, sampling is not performed at depths beyond those reachable by marine mammals. The received per-pulse or per-second SEL at a surface sampling location is taken as the maximum value that occurs over all samples within the water column, i.e., the maximum-over-depth received per-pulse SEL. These maximum-over-depth per-pulse SEL are presented as colour contours around the source.

An inherent variability in measured sound levels is caused by temporal variability in the environment and the variability in the signature of repeated acoustic impulses (sample sound source verification results is presented in Figure E-2). While MONM's predictions correspond to the averaged received levels, cautionary estimates of the threshold radii are obtained by shifting the best fit line (solid line, Figure E-2) upward so that the trend line encompasses 90% of all the data (dashed line, Figure E-2).

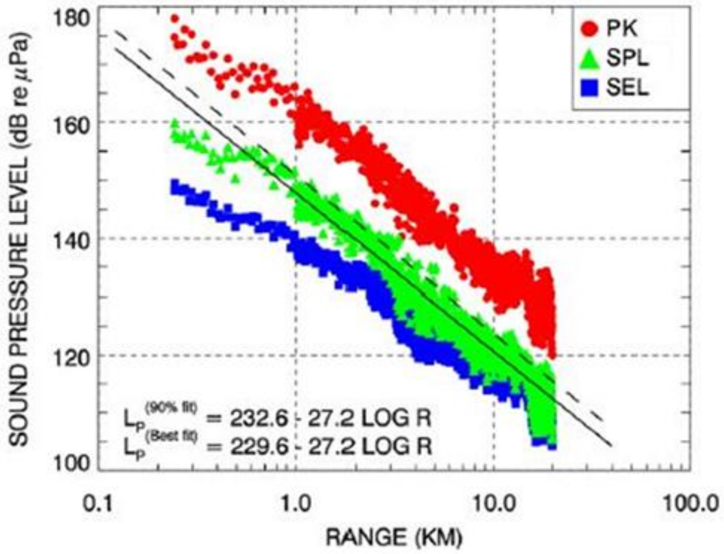

Figure E-2. PK and SPL and per-pulse SEL versus range from a 20 in^3 seismic source. Solid line is the least squares best fit to SPL. Dashed line is the best fit line increased by 3.0 dB to exceed 90% of all SPL values (90th percentile fit) (Ireland et al. 2009, Figure 10).

E.4. Wavenumber Integration Model

Sound pressure levels near the seismic source were modelled using JASCO's VSTACK wavenumber integration model. VSTACK computes synthetic pressure waveforms versus depth and range for arbitrarily layered, range-independent acoustic environments using the wavenumber integration approach to solve the exact (range-independent) acoustic wave equation. This model is valid over the full angular range of the wave equation and can fully account for the elasto-acoustic properties of the sub-bottom. Wavenumber integration methods are extensively used in the field of underwater acoustics and seismology where they are often referred to as reflectivity methods or discrete wavenumber methods. VSTACK computes sound propagation in arbitrarily stratified water and seabed layers by decomposing the outgoing field into a continuum of outward-propagating plane cylindrical waves. Seabed reflectivity in the model is dependent on the seabed layer properties: compressional and shear wave speeds, attenuation coefficients, and layer densities. The output of the model can be post-processed to yield estimates of the SEL, SPL, and PK.

VSTACK accurately predicts steep-angle propagation in the proximity of the source, but it is computationally slow at predicting sound pressures at large distances due to the need for smaller wavenumber steps with increasing distance. Additionally, VSTACK assumes range-invariant bathymetry with a horizontally stratified medium (i.e., a range-independent environment) which is azimuthally symmetric about the source. VSTACK is thus best suited to modelling the sound field near the source.

Appendix F. Methods and Parameters

This section describes the specifications of the seismic source that was used at all sites and the environmental parameters used in the propagation models.

F.1. Estimating Range to Thresholds Levels

Sound level contours were calculated based on the underwater sound fields predicted by the propagation models, sampled by taking the maximum value over all modelled depths above the sea floor for each location in the modelled region. The predicted distances to specific levels were computed from these contours. Two distances relative to the source are reported for each sound level: 1) R_{max}, the maximum range to the given sound level over all azimuths, and 2) $R_{95\%}$, the range to the given sound level after the 5% farthest points were excluded (see examples in Figure F-1).

The $R_{95\%}$ is used because sound field footprints are often irregular in shape. In some cases, a sound level contour might have small protrusions or anomalous isolated fringes. This is demonstrated in the image in Figure F-1(a). In cases such as this, where relatively few points are excluded in any given direction, R_{max} can misrepresent the area of the region exposed to such effects, and $R_{95\%}$ is considered more representative. In strongly asymmetric cases such as shown in Figure F-1(b), on the other hand, $R_{95\%}$ neglects to account for significant protrusions in the footprint. In such cases R_{max} might better represent the region of effect in specific directions. Cases such as this are usually associated with bathymetric features affecting propagation. The difference between R_{max} and $R_{95\%}$ depends on the source directivity and the non-uniformity of the acoustic environment.

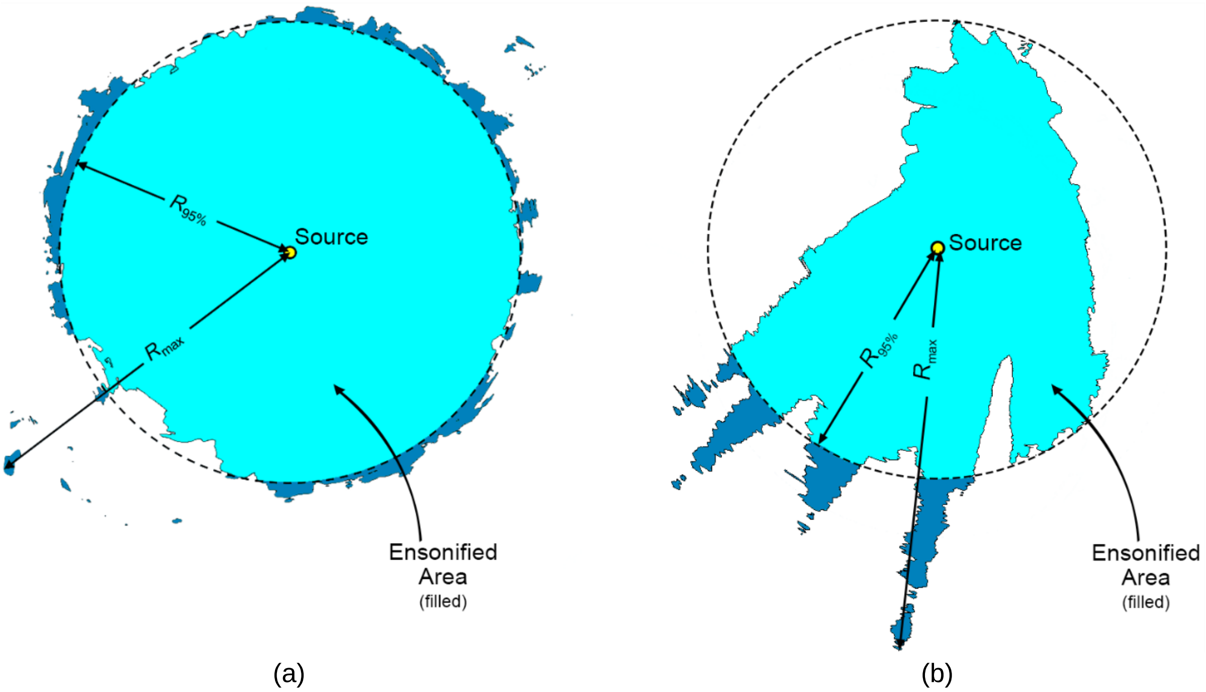

Figure F-1. Sample areas ensonified to an arbitrary sound level with R_{max} and $R_{95\%}$ ranges shown for two different scenarios. (a) Largely symmetric sound level contour with small protrusions. (b) Strongly asymmetric sound level contour with long protrusions. Light blue indicates the ensonified areas bounded by $R_{95\%}$; darker blue indicates the areas outside this boundary which determine R_{max}.

F.2. Estimating SPL from Modelled SEL Results

The per-pulse SEL of sound pulses is an energy-like metric related to the dose of sound received over a pulse's entire duration. The pulse SPL on the other hand, is related to its intensity over a specified time interval. Seismic pulses typically lengthen in duration as they propagate away from their source, due to seafloor and surface reflections, and other waveguide dispersion effects. The changes in pulse length, and therefore the time window considered, affect the numeric relationship between SPL and SEL. This study has applied a fixed window duration to calculate SPL (T_{fix} = 125 ms; see Appendix A.1), as implemented in Martin et al. (2017b). Full-waveform modelling was used to estimate SPL, but this type of modelling is computationally intensive, and can be prohibitively time consuming when run at high spatial resolution over large areas.

For the current study, FWRAM (Appendix E.2) was used to model synthetic seismic pulses over the frequency range 5–1024 Hz. This was performed along all broadside and endfire radials at modelled site 1. FWRAM uses Fourier synthesis to recreate the signal in the time domain so that both the SEL and SPL from the source can be calculated. A 125 ms fixed time window positioned to maximise the SPL over the pulse duration was applied. The resulting SEL-to-SPL offsets were averaged in 0.01 km range bins along each modelled radial and depth, and the 90th percentile was selected at each range to generate a generalised range-dependent conversion function for the site. The range-dependent conversion function was then applied to predicted per-pulse SEL results from MONM to model and map SPL values. Figure F-2 shows the conversion offsets for the WHP site; the spatial variation is caused by changes in the received airgun pulse as it propagates from the source

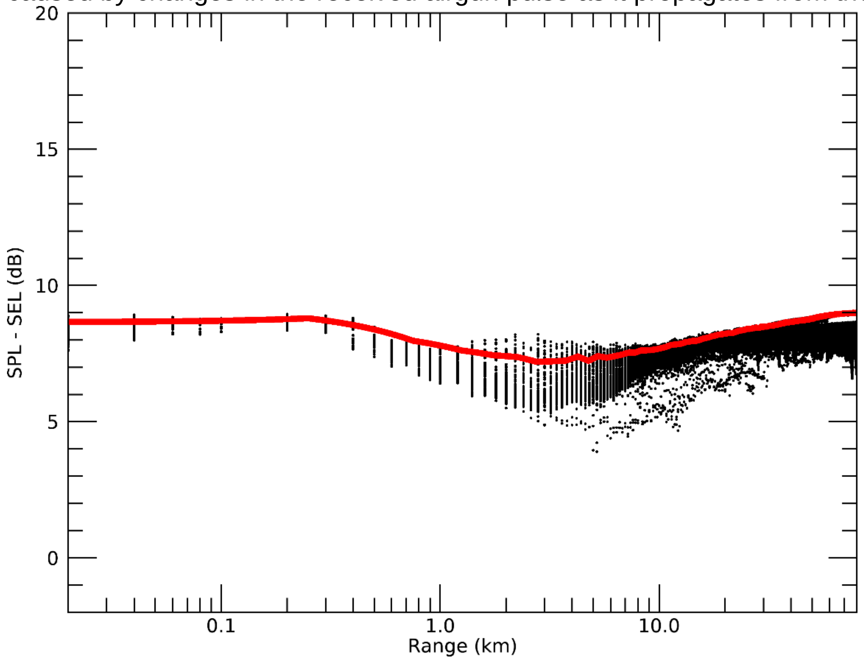

Figure F-2. Range-and-depth-dependent conversion offsets for converting SEL to SPL for VSP pulses for Dorado WHP site. Black dots are the modelled differences between SEL and SPL across different radials and receiver depths; the solid red line is the 90th percentile of the modelled differences at each range.

F.3. Environmental Parameters

F.3.1. Bathymetry

Water depths throughout the modelled areas were extracted from a dataset provided by the client (Berry 2019) and these data were re-gridded from several overlapping sub dataset using bathymetry acquired during recent surveys in the area of the dorado development project. The Australian Bathymetry and Topography Grid, a 9 arc-second grid data (Whiteway 2009) was used as a base layer for re-gridding. Bathymetry data were re-gridded onto a Map Grid of Australia (MGA) coordinate projection (Zone 54) with a regular grid spacing of 100 × 100 m. For large the scale overview inset maps in the report, Australian Bathymetry and Topography Grid, a 9 arc-second grid data (Whiteway 2009) was used to supplement client supplied data.

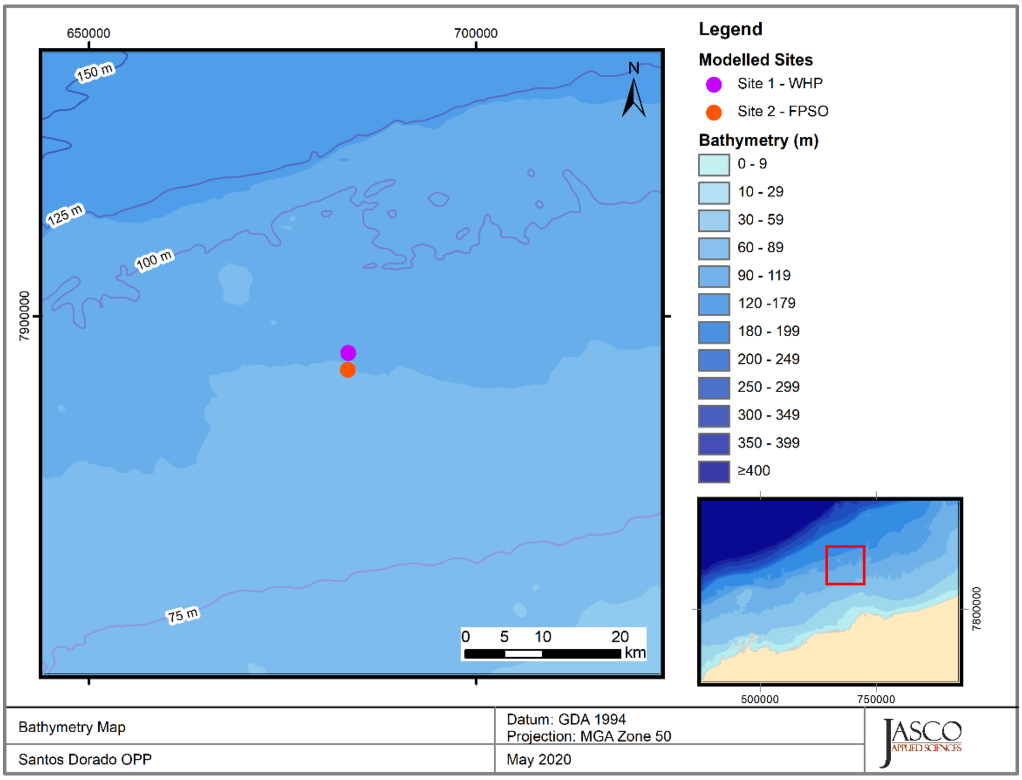

Figure F-3. Bathymetry in the modelled area.

F.3.2. Sound speed profile

The sound speed profile in the area was derived from temperature and salinity profiles from the U.S. Naval Oceanographic Office's *Generalized Digital Environmental Model V 3.0* (GDEM; Teague et al. 1990, Carnes 2009). GDEM provides an ocean climatology of temperature and salinity for the world's oceans on a latitude-longitude grid with 0.25° resolution, with a temporal resolution of one month, based on global historical observations from the U.S. Navy's Master Oceanographic Observational Data Set (MOODS). The climatology profiles include 78 fixed depth points to a maximum depth of 6800 m (where the ocean is that deep). The GDEM temperature-salinity profiles were converted to sound speed profiles according to Coppens (1981).

Mean monthly sound speed profiles were derived from the GDEM profiles within a 100 km box radius encompassing all modelled sites. The July sound speed profile is expected to be most favourable to longer-range sound propagation during the proposed survey time frame. As such, July was selected for sound propagation modelling to ensure precautionary estimates of distances to received sound level thresholds. Figure F-4shows the resulting profile used as input to the sound propagation modelling.

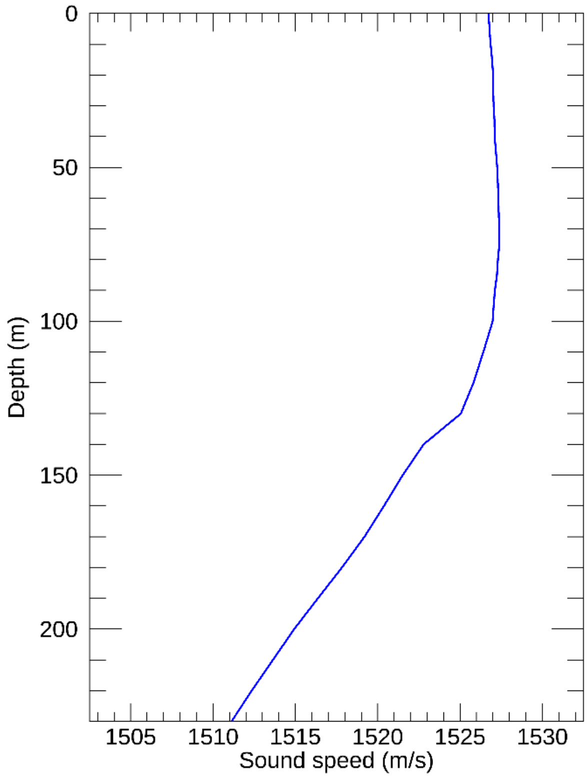

Figure F-4. The modelling sound speed profile corresponding to July Profiles are calculated from temperature and salinity profiles from *Generalized Digital Environmental Model* V 3.0 (GDEM; Teague et al. 1990, Carnes 2009).

F.3.3. Geoacoustics

For the modelled sites the seabed in the area has been described as a calcarenite substrate overlain with a layer of sand (NGI 2017). This is very similar to a profile described in association with measurement data (McCauley et al. 2016), and other modelling studies in the region (AIMS 2018). The geoacoustic parameters used for modelling at Sites 1–2 (Table F-1) are based on Duncan et al. (2009).

Table F-1. Geoacoustic profile for the Sites 1–2

Depth below seafloor (m)	Predicted lithology	Density (g/cm³)	Compressional wave		Shear wave	
			Speed (m/s)	Attenuation (dB/λ)	Speed (m/s)	Attenuation (dB/λ)
0–10	Medium carbonate sand	1.8	1700	0.8	350	2.5
>10	Calcarenite	2.4	2800	0.1		

F.4. Model Validation Information

Predictions from JASCO's propagation models (MONM, FWRAM, and VSTACK) have been validated against experimental data from a number of underwater acoustic measurement programs conducted by JASCO globally, including the United States and Canadian Artic, Canadian and southern United States waters, Greenland, Russia and Australia (Hannay and Racca 2005, Aerts et al. 2008, Funk et al. 2008, Ireland et al. 2009, O'Neill et al. 2010, Warner et al. 2010, Racca et al. 2012a, Racca et al. 2012b, Matthews and MacGillivray 2013, Martin et al. 2015, Racca et al. 2015, Martin et al. 2017a, Martin et al. 2017b, Warner et al. 2017, MacGillivray 2018, McPherson et al. 2018, McPherson and Martin 2018).

In addition, JASCO has conducted measurement programs associated with a significant number of anthropogenic activities which have included internal validation of the modelling (including McCrodan et al. 2011, Austin and Warner 2012, McPherson and Warner 2012, Austin and Bailey 2013, Austin et al. 2013, Zykov and MacDonnell 2013, Austin 2014, Austin et al. 2015, Austin and Li 2016, Martin and Popper 2016).

Appendix G. Additional Results

G.1. WHP Piling SEL Contour Maps

Maps of the per-strike SEL results associated with the three modelled penetration depths are shown in Figures G-1–3 for the MHU 600T hammer.

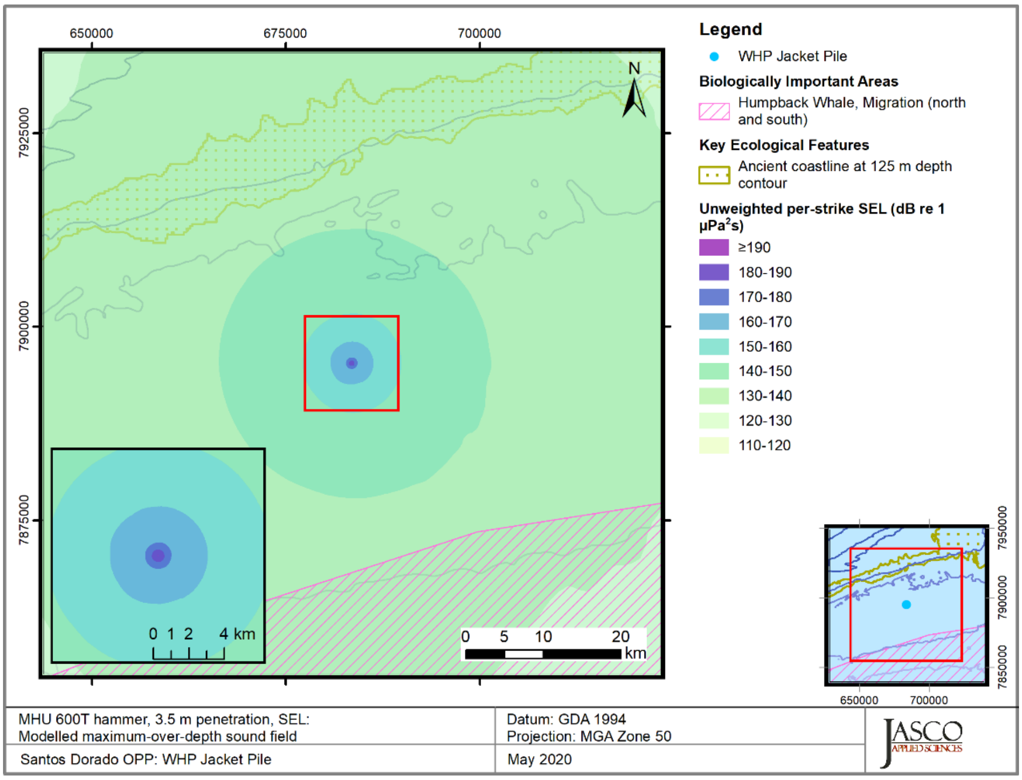

Figure G-1. *WHP piling, per-strike SEL, 3.5 m penetration depth*: Sound level contour map showing maximum-over-depth results.

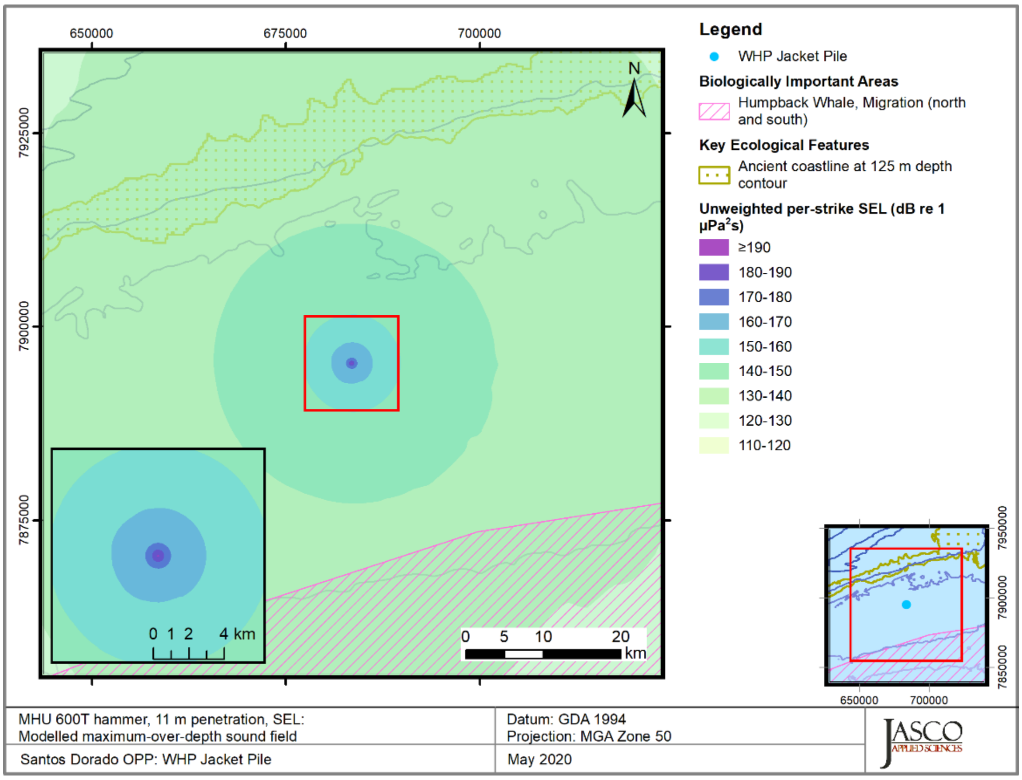

Figure G-2. *WHP piling, per-strike SEL, 11 m penetration depth*: Sound level contour map showing maximum-over-depth results.

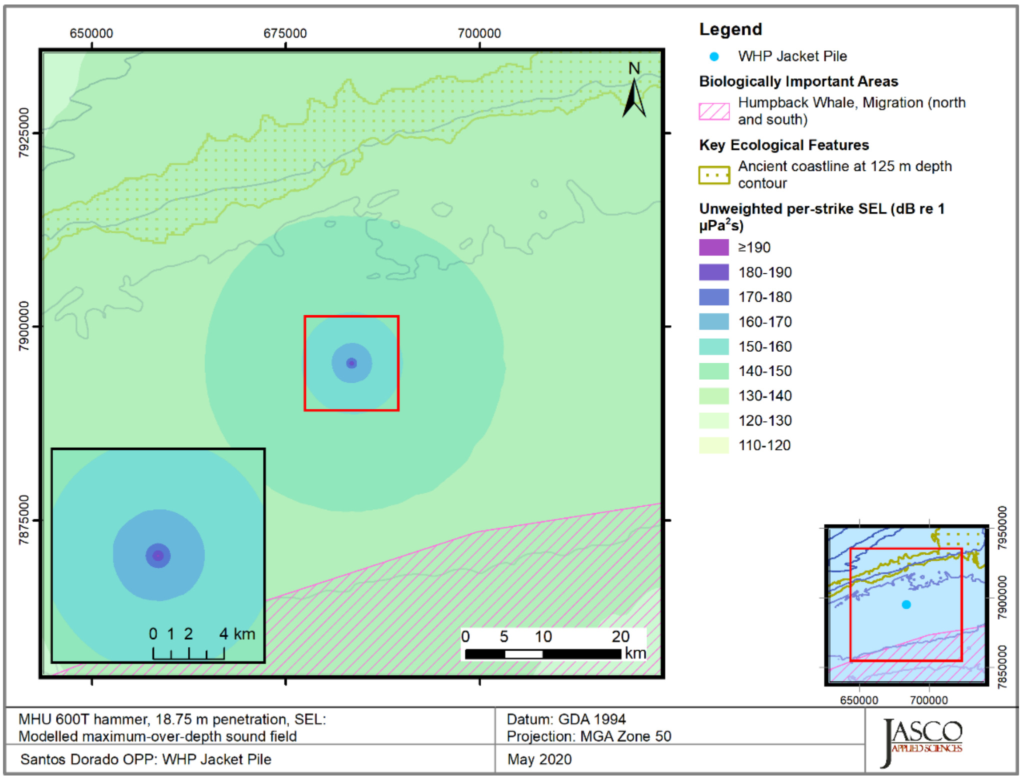

Figure G-3. *WHP piling, per-strike SEL, 18.75 m penetration depth*: Sound level contour map showing maximum-over-depth results.

G.2. FPSO Piling SEL Contour Maps

Maps of the per-strike SEL results associated with the three modelled penetration depths are shown in Figures G 4–6 for the MHU 600T hammer.

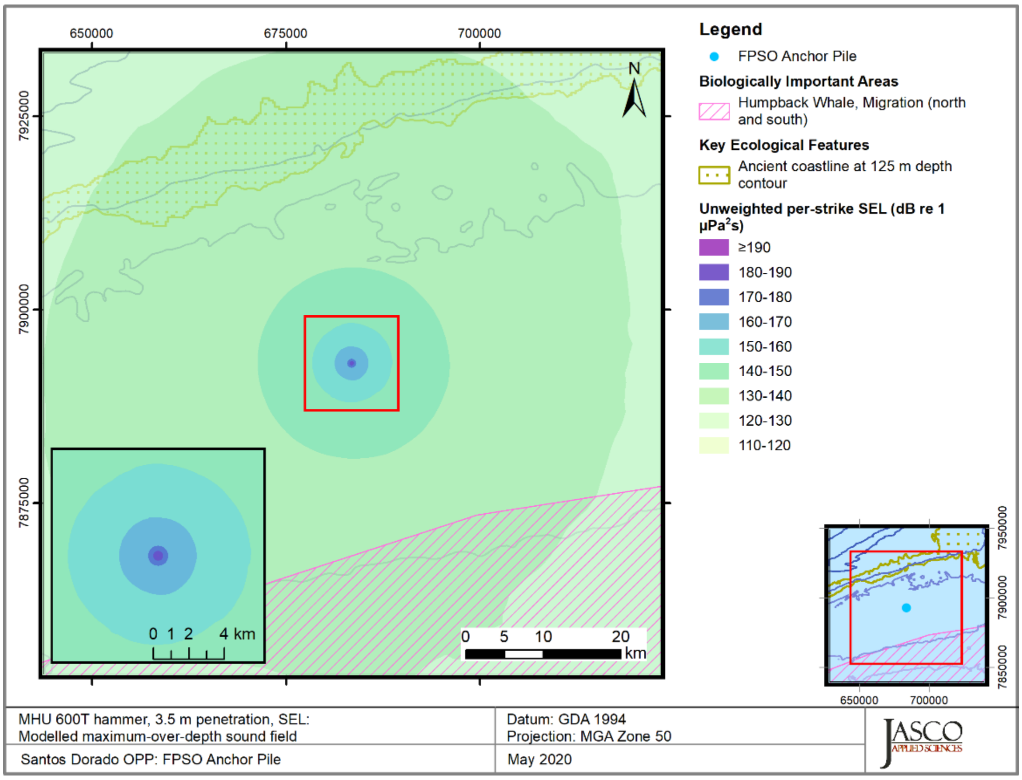

Figure G-4. *FPSO anchor piling, per-strike SEL, 3.5 m penetration depth*: Sound level contour map showing maximum-over-depth results.

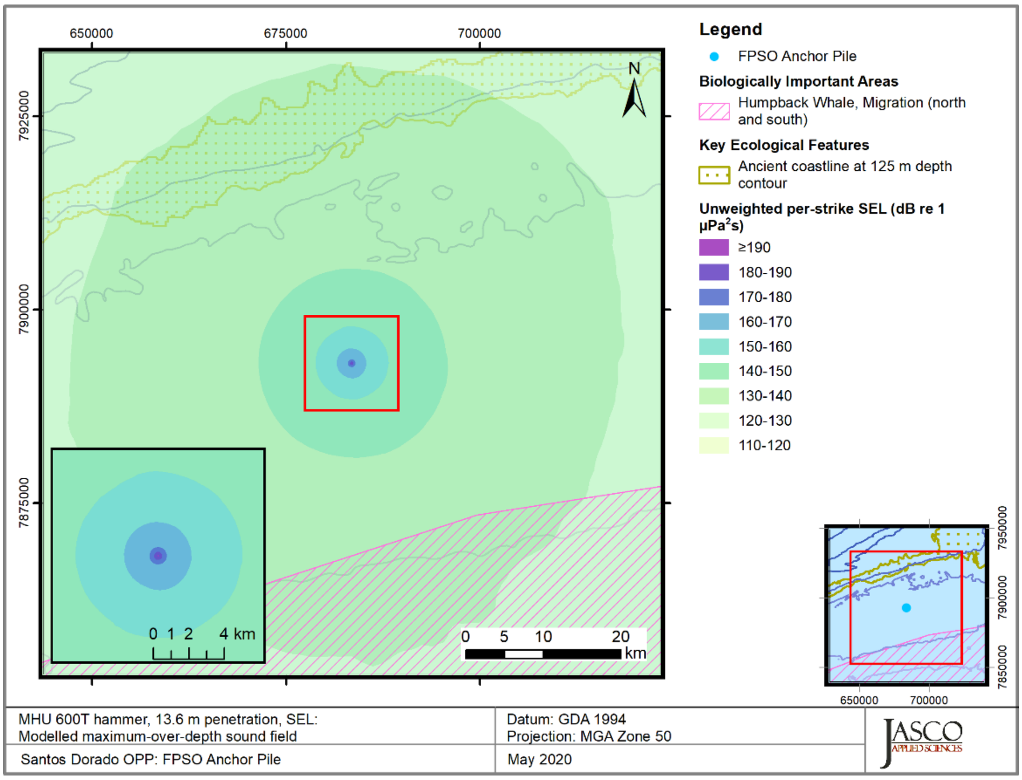

Figure G-5. *FPSO anchor piling, per-strike SEL, 13.6 m penetration depth*: Sound level contour map showing maximum-over-depth results.

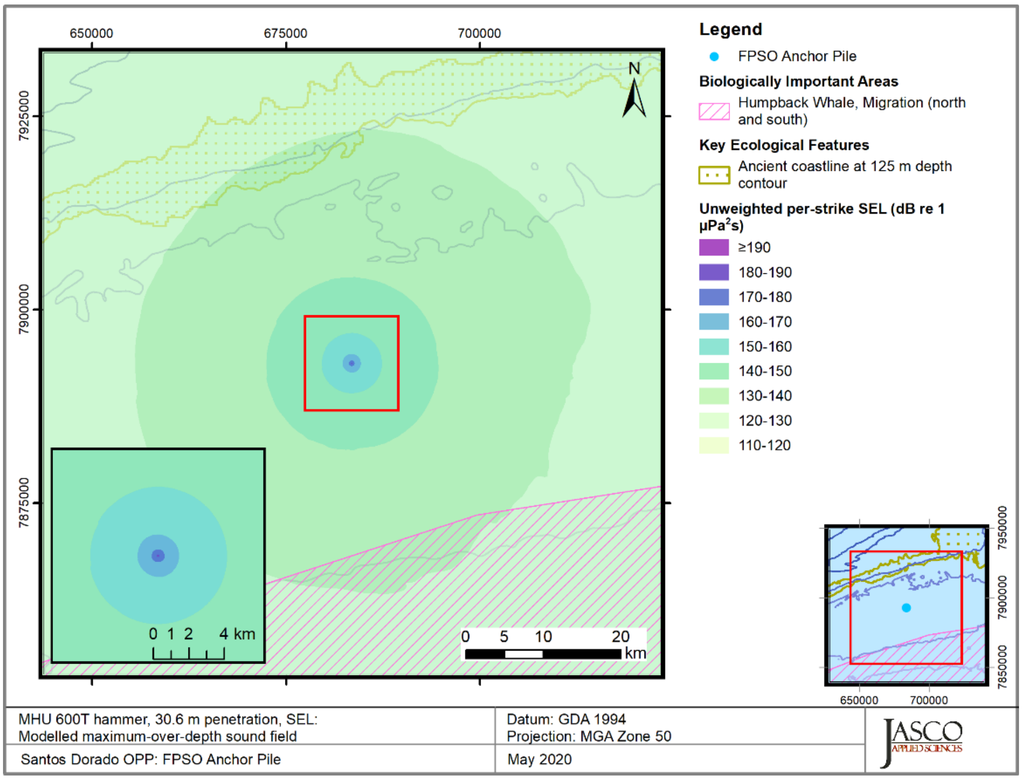

Figure G-6. *FPSO anchor piling, per-strike SEL, 30.6 m penetration depth*: Sound level contour map showing maximum-over-depth results.

G.3. WHP VSP SEL Contour Map

1. Purpose

Petroleum activities undertaken by Santos may produce noise and associated vibrations in air, underwater and beneath the earths' surface. Activities and facilities associated with the petroleum activities generate routine acoustic emissions during drilling, installation and commissioning, and operations. This document has been prepared to support environment impact and risk assessment for underwater acoustic emissions as a result of the following Santos petroleum activities:

- Vertical Seismic Profiling
- Offshore Pile Driving (Impact Driving)
- Drilling
- Vessel Operations

The document summarises relevant research completed to date and aims to:

- characterise the noise sources associated with each activity, and the potential impacts from the noise;
- describe marine fauna sensitivity to the noise sources;
- provide an overview of the existing knowledge and understanding of the potential noise-induced effects; and
- assist with adopting appropriate thresholds for marine animals for impact assessment of the petroleum activities.

As this document supports Santos environment risk assessments, it will be reviewed when it is used to support Santos environment risk assessment processes such as the preparation of environment plan or the assessment of environment risk associated with specific petroleum activities.

This document does not represent all potential sources of underwater sound associated with Santos petroleum activities, however it includes all of those relevant to this impact assessment.

2. Background

Sound is a natural phenomenon occurring in all aquatic environments, and marine fauna have evolved and adapted in the presence of this natural soundscape. Natural sounds vary constantly due to biological, oceanographic, and meteorological processes. Anthropogenic activities introduce additional sound into the water. The multitude of parameters influencing the natural and anthropogenic contributions to the overall soundscape create a complex scenario for an impact assessment.

Acoustic signals have evolved as the principal mode of information transmission for many marine species. Marine invertebrates and sea turtles are sensitive to sound, but it remains unclear if and to what extent underwater sound has a functional role for these species. The sensitivity of fish to sound varies, but sound plays an important role in their life. Many fish species can hear and use sounds for learning about their environment (Ladich and Fay 2013). including to actively communicate, most often aiming at nearby prospective mates (Lobel et al. 2010) and mainly associated with two behavioural contexts: reproduction and aggression. The hearing system of marine mammals is very sensitive, and these animals use underwater sound passively when listening to the environment and actively when communicating. It is also well known that odontocetes (toothed whales) use sound actively when foraging.

The sounds that marine animals hear and generate vary in characteristics such as dominant frequency, bandwidth, energy, temporal pattern, and directivity. Just as many terrestrial animals integrate multiple stimuli from their visual landscape, marine life must discriminate a signal (a meaningful sound) among multiple stimuli in their acoustic seascape. Anthropogenic sounds can affect marine life in a variety of ways.

The potential for sound-induced impacts varies with the temporal and acoustic characteristics of the sound source, sound propagation characteristics of the physical environment, and biological factors. Biological factors include the hearing range of the species (broad range and most sensitive frequencies), an animals' state of activity (feeding versus resting or migrating), individual hearing loss, previous exposure to sound type (habituation), life history stage, reproductive status, and health status all contribute to the impacts of anthropogenic sound on marine animals. Past studies on the reactions of marine mammals to anthropogenic sound have shown widely varied responses, depending on the individual, context, age, gender, and activity in which the animals were engaged (Simmonds et al. 2003, Ellison et al. 2012).

Relevant to all marine fauna four zones of noise-influence with decreasing size and increasing intensity of the signal can be defined (see Section 6). With the highest levels of sound at the sound source at the centre of the model, the noise level and severity of noise-induced impacts decline with increasing distance from the source. The four zones of acoustic influence are:

- *Audibility*: Signal source levels decrease with range from a source due to propagation losses. Their audibility is limited by the signal dropping either below the animal's hearing threshold or below ambient sound levels.
- *Responsiveness*: The zone of behavioural response is generally smaller than the zone of audibility, as an animal is not likely to respond to a sound that is barely detectable.
- *Masking*: This zone overlaps with zone of responsiveness. Masking occurs when a noise impedes the ability of the animal to perceive a biologically relevant signal.
- *Injury or impairment*: Direct physical injury resulting in mortality, temporary or permanent impairment of the auditory (hearing) system, or (non-lethal) injury to non-auditory organs.

3. Underwater Sound

Sound is always present in the underwater environment. It is naturally caused by biological sources such as whales, fish, and invertebrates (e.g., snapping shrimp) and by meteorological and oceanographical sources (such as rain, wind driven waves, and currents). The existing sound in an environment can be summed up as the ambient sound or soundscape. While the term ‘sound’ is objective, the term ‘noise’ can be considered as the ‘unwanted’ sound, i.e., sound that has an impact on a receptor. Underwater sound is a vibration wave that can be measured in terms of two distinct physical components—sound pressure and particle motion. These serve as input to the sensory systems in marine animals and different species (or taxa) developed sensors for either one of these sound components, and some are sensitive to both. While marine mammal hearing is sensitive to sound pressure, fish and marine invertebrates sense particle motion and some fish species are capable of detecting both. Anthropogenic sound is emitted by almost all activities at sea, either intentional (e.g. an echosounder) or as a by-product (e.g. shipping). Assessing the impact of anthropogenic underwater noise on marine receptors requires an understanding of the basic physical principles of underwater sound. A brief overview of the most important aspects and most relevant terms and metrics can be found in Appendix A.

The following section gives an introduction into sound propagation and important differences between sound types and provides an overview of the acoustic characteristics of the sound sources considered in this technical appendix.

3.1. Sound Propagation

Sound is altered by the aquatic environment as it propagates away from a source to a receiver some distance away. Factors influencing propagation include the bathymetry and composition of the seabed and the temperature and salinity of the water column. The physical processes affecting sound along its propagation path are attenuation due to geometric spreading, reflection, scattering at the sea surface and seabed, refraction due to sound speed gradients, and absorption by sea water. Each factor substantially changes the acoustic characteristics of the emitted signal and its propagation from the sound source to the receiver.

A given sound emitted in different locations, or in the same location at different times, may therefore be detectable for varying distances, depending on regional and temporal changes in sound propagation conditions (Richardson et al. 1995). In general, low-frequency sound (<200 Hz) is transmitted most efficiently in deep water due to sound channels within the water column (Jensen et al. 2011), while intermediate-frequency sound (100–1000 Hz) is transmitted most efficiently in shallower coastal waters, such as those less than 200 m deep (Richardson et al. 1995). However, specifics depend upon the local geology and sound speed profiles (Jensen et al. 2011).

3.2. Impulsive Sounds versus Non-Impulsive Sound

Impulsive and non-impulsive sounds are primarily distinguished by their temporal pattern. Impulsive or ‘pulsed’ sounds can be described as discrete sounds (e.g., single pulses) and sometimes intermittent sounds (e.g., multiple pulses) produced by sources such as seismic airguns and pile driving. These sounds, sometimes also termed transients, are typically brief signals consisting of a high peak sound pressure with a rapid rise time and a rapid decay (NIOSH 1998). However, there are no quantitative metrics specified to identify and define the impulsiveness of acoustic signals, which makes it problematic to characterise the impulsiveness of their acoustic signatures (discussed further in Section 5.2.1).

Non-impulsive sounds, which can be intermittent or continuous, are produced by sound sources such as ships and marine vibrator signals. Non-impulsive sounds have a longer duration than impulsive ones, and they usually do not have the high peak sound pressure and rapid rise and decay time that impulsive sounds have (NIOSH 1998). However, especially in respect to their auditory effects on marine fauna, the term non-impulsive does not imply long duration signals.

3.3. Metrics

Three pressure related metrics are commonly used for analysing and describing the acoustic characteristics of underwater sound and for evaluating underwater sound impacts on marine fauna: peak pressure (PK), sound pressure level (SPL), and sound exposure level (SEL) (see Appendix A). The period of accumulation associated with SEL must always be defined. Subscripts indicate any applied frequency weighting (see Section 5.1.4.2 for details). Particle motion can be measured in terms of three different (but related) quantities: displacement, velocity, or acceleration (Appendix A.4), however the relevance of the different quantities to effects of fauna is currently under investigation, and no cumulative metric for particle motion currently exists.

For impulsive sources, SPL is gradually being supplemented or replaced by fast time-weighted average SPL. The publication of ISO 18405 Underwater Acoustics – Terminology (ISO 2017) provides a dictionary of underwater bioacoustic terms (previous standards: IEC 1994, ANSI S1.1-2013 R2013). This technical appendix follows the definitions and conventions of ISO (2017) unless directly referring to metrics used in published literature.

The US National Marine Fisheries Service (NMFS) issued a Technical Guidance document providing regulatory criteria for noise exposure of marine mammals (NMFS 2018). The Technical Guidance is using a slightly different notation for the acoustic metrics (Table 1) with a dual criterion for assessing injurious exposures, including a peak (unweighted/flat) sound pressure level metric PK (L_{pk}) and a cumulative sound exposure level $\mathrm{SEL}_{\mathrm{cum}}$ ($\mathrm{SEL}_{\mathrm{24h}}$) metric with frequency weighting. The acoustic metric terminology used in Southall et al. (2019) is equivalent to this guidance. Following the ISO standard, the L_{pk} as used by NMFS and Southall et al. (2019) is denoted as PK in this technical appendix. The $\mathrm{SEL}_{\mathrm{cum}}$ metric as used by NMFS and Southall et al. (2019) describes the sound energy received by a receptor over 24 hours. Accordingly, following the ISO (2017) standard, this is denoted as $\mathrm{SEL}_{\mathrm{24h}}$ in this Technical Appendix. There are no defined impact assessment criteria for particle motion, and relevant metrics and reporting guidelines are a current research topic, therefore no summary is presented.

Table 1. Acoustic metrics used in this Technical Appendix as compared to other publications.

Metric	NMFS (2018) and Southall et al. (2019)	Technical appendix (as per ISO 2017)		Unit
		Abbreviation in main text	Symbol in equations/tables	
Sound pressure level	n/a	SPL	L_p	decibel (dB) re 1 micropascal (μPa)
Peak sound pressure level	PK	PK	L_{pk}	dB re 1 μPa
Sound exposure level (per pulse)	n/a	Per-pulse SEL	L_E	dB re 1 $\mu\mathrm{Pa}^2\cdot\mathrm{s}$
Sound exposure level (accumulated over time), $\mathrm{SEL}_{\mathrm{time\text{-}period}}$	$\mathrm{SEL}_{\mathrm{cum}}$	$\mathrm{SEL}_{\mathrm{24h}}$	$L_{E,\mathrm{24h}}$	dB re 1 $\mu\mathrm{Pa}^2\cdot\mathrm{s}$
Source level	SL	SL	$L_{\mathrm{S,pk}}$ $L_{\mathrm{S},p}$ $L_{\mathrm{S,E}}$	dB re 1 μPa·m (Peak source pressure level, SPL source level) or dB 1 $\mu\mathrm{Pa}^2\mathrm{m}^2\mathrm{s}$ (Per-pulse source SEL)
Particle acceleration (not accumulated)	n/a	n/a	n/a	$\mathrm{m/s^2}$, $\mu\mathrm{m/s^2}$, and $\mathrm{nm/s^2}$, and logarithmic scale (dB) relative to these units

3.4. Sound Pressure versus Particle Motion

The particle motion generated by an active sound source refers to the vibration of the particles that make up the media when a sound is present (Martin et al. 2016). It can be quantified in terms of particle velocity, particle displacement, and particle acceleration (Appendix A.3). These are vector quantities (having magnitude and direction) inferred from the sound pressure (a scalar quantity having only magnitude).

While often collectively reported and/or referred to as particle motion, marine animals seem to be most sensitive to particle acceleration. The units for this metric differ between m/s^2, $\mu m/s^2$, and nm/s^2 and can also be reported in a logarithmic scale (decibel, dB) relative to any of these units.

In a free sound field such as in mid-water in the open ocean (i.e., in the absence of acoustic boundaries such as sea surface or sea floor) and within the acoustic far field of the sound source, the sound pressure radiated from a simple acoustic source falls off as $1/r$, where r is the distance from the source (Ainslie and de Jong 2016). Under these conditions, particle motion is directly correlated with sound pressure. Estimations of particle motion based on sound pressure measurements, however, can lead to substantial errors (Gray et al. 2016), as sound pressure measured under different conditions may be accompanied by very different levels of particle motion (Popper et al. 2019).

4. Sources of Anthropogenic Noise

This document has been prepared to support environment impact and risk assessment for underwater acoustic emissions as a result of the following Santos petroleum activities:

- Vertical Seismic Profiling
- Offshore Pile Driving (Impact Driving)
- Drilling
- Vessel Operations

Each of these sources is discussed in this section as relevant to the current assessment.

4.1. Vertical Seismic Profiling

Vertical Seismic Profiling (VSP) has four important roles to play in assessing the rock and fluids close to the borehole:

1. to provide in situ rock properties in depth, particularly seismic velocity, impedance, anisotropy, and attenuation.
2. to assist in understanding seismic wave propagation (e.g., source signatures, multiples, and conversions).
3. to make well understood reflectivity images in depth, and
4. to use all of the above in further surface seismic data processing and interpretation (Stewart 2001).

The acoustic sources used in VSPs are seismic airguns, which are essentially stainless-steel cylinders charged with high-pressure air. An acoustic signal is generated when that air is (almost instantaneously) released into the surrounding water column (Figure 1). For a single airgun, the amplitude of its acoustic signal is a function of the volume and pressure of the air inside the airgun and the ambient pressure (i.e. its depth below the water surface). The pressure inside the cylinder far exceeds the ambient pressure and, when triggered, generates an oscillating bubble around the release aperture. This difference in pressure causes the bubble to rapidly expand in the water, and this initial expansion generates a radiating impulsive pressure wave, typically broadband in nature. Because of the momentum of its expansion, the bubble grows until the internal pressure becomes less than the ambient pressure. At that point, the bubble starts to collapse. Elasticity in the process generates the characteristic oscillating pressure cycle, which continues until the bubble reaches the sea surface and vents into the atmosphere. Given that energy is lost during each cycle, the bubble behaves as a damped oscillator, producing increasingly smaller bubble pulses with each cycle.

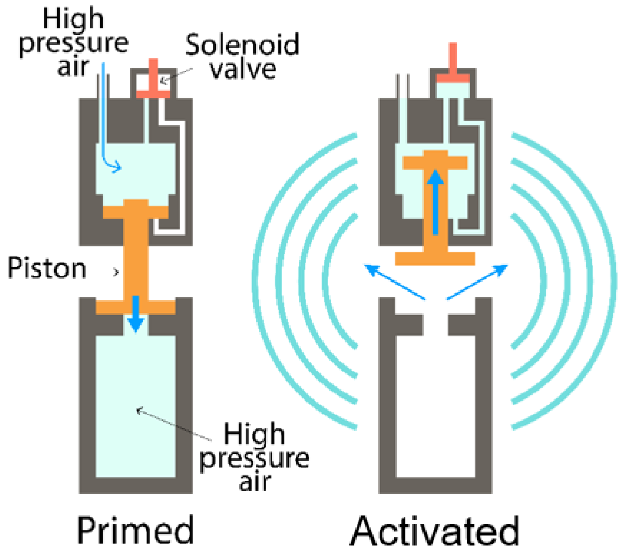

Figure 1. Schematic showing the functioning of a seismic airgun.

4.1.1. Operational Configurations

A VSP survey is typically conducted at each well after a final depth is reached (but may be conducted at a shallower depth depending upon operations) before a production tubing/casing is placed in the well bore or the well is abandoned.

The following are typical types of VSP surveys:

- Zero-offset or check-shot survey, when the seismic source is placed very near to the vertical array of sensors.
- Walk-away survey, when the seismic source is placed in a series of positions along a radial line from the vertical array of sensors
- Three-dimensional (3-D) VSP survey, when the source is deployed in an area surrounding the vertical array of sensors.
- Inverse survey, where the locations of the source and receiver are reversed.

The most common type of VSP in Australian waters are zero-offset surveys suspended from a crane onboard a platform (Figure 2), followed by walk-away surveys; each survey type is designed to acquire specific information.

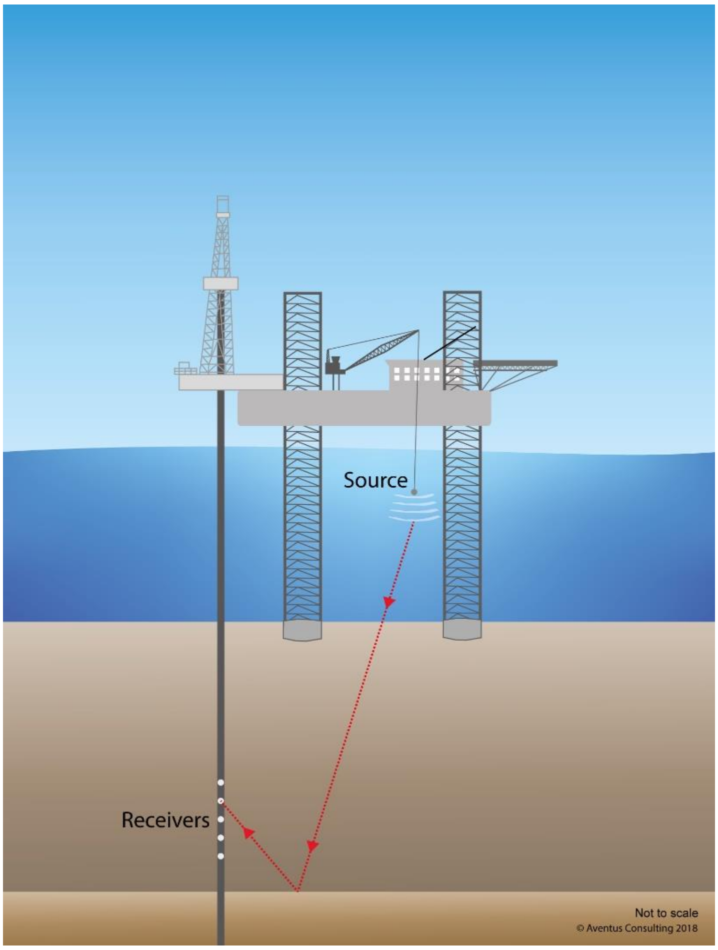

Figure 2. Example of a zero-offset VSP configuration (supplied by Adventus Consulting).

Typical VSP arrays can be configured in a number of ways, depending on the number of airguns within the array, e.g., 2 x 150, 3 x 150, 2 x 250, and 3 x 350 in^3, operating at 1800 psi (Nakanishi 2009). When there are only two airguns in an array, they are set at the same depth; however, when there are more than two, a single airgun is often positioned above the other two to focus the array signature downwards.

The total duration of a VSP survey depends on the specific type of survey, the survey objectives, and the equipment used. For a zero-offset survey or a walk-away survey, the duration may be less than a day. Each survey is different, with timings set by operational considerations. However, a common approach for a zero-offset survey is for the airguns to be activated four to eight times for a period of 20 s, followed by a 5- to 20-min quiet time during which the sensor string in the borehole or well is raised. The airguns are then activated again for four to eight times for 20 s and so on until the survey is completed.

4.1.2. Acoustic emissions

The small arrays used for VSP produce most energy at frequencies below 500 Hz (Figure 3). Airgun signatures consist of a strong primary peak, related to the initial release of high-pressure air, followed by a series of pulses associated with bubble oscillations. For all types of arrays, frequency-dependent peaks and nulls in the spectrum result from interference among airguns in the array, and they correspond with the volumes and locations of the airguns relative to each other. Therefore, each array has a unique spectrum.

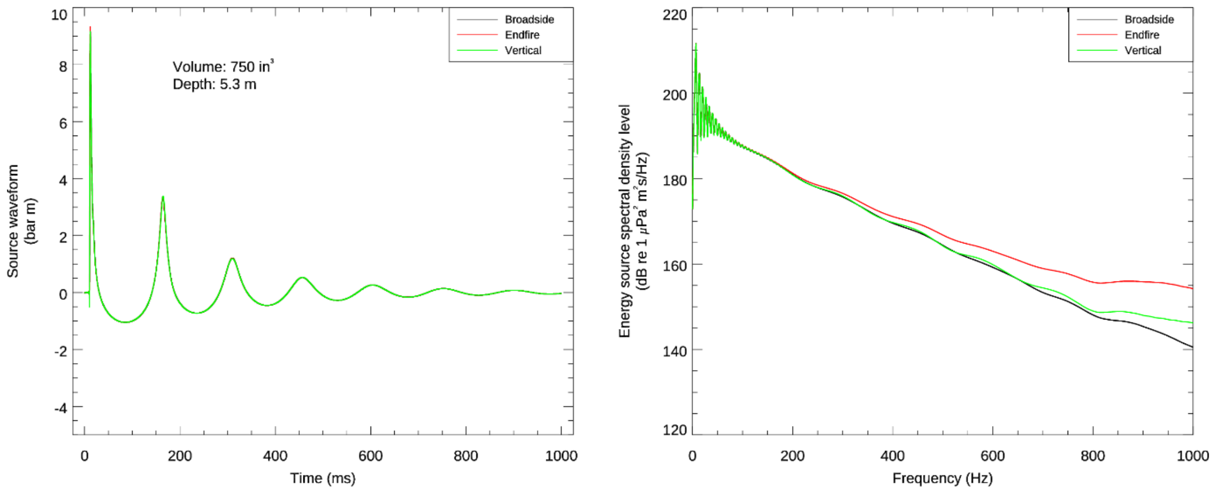

Figure 3. Predicted source level details for an example 750 in^3 array at a 5.3 m operational depth.(Left) the overpressure signature and (right) the power spectrum for in-plane horizontal (broadside), perpendicular (endfire), and vertical directions.

4.2. Offshore Pile Driving

Pile driving operations can be conducted from above and below the sea surface. Pile driving is often required for installing anchor points for floating and fixed offshore facilities drill rigs, foundation supports, and jetty/ wharf infrastructure. There are numerous methods of pile driving, however, only impact piling is included in this document.

4.2.1. Operational Configurations

Impact pile driving is carried out using an impact hammer, which consists of a falling ram that repeatedly strikes the top of a pile to drive it into the ground. When the ram strikes the pile, the impact creates stress waves traveling down the length of the pile, which couples with the surrounding medium, radiating acoustic energy into the water. Pile driving also generates vibration waves in the sediment, which can radiate acoustic energy back into the water from the seabed. The sound from impact pile driving is impulsive - transient, repetitive, and discontinuous (Reinhall and Dahl 2011, McPherson et al. 2017). Depending upon the pile and hammer combinations, the strike interval can range from one to two seconds.

4.2.2. Acoustic Emissions

Sound levels produced by pile driving depend on several interdependent factors such as pile size, hammer strike energy, and geoacoustic properties of the seabed. Field measurements of pile driving show that source, or near-source levels are typically in the 210 to 250 dB re 1 µPa range (McHugh 2005, Tougaard et al. 2009, Bailey et al. 2010) and the frequency is predominantly <1 kHz (Robinson et al. 2007, Tougaard et al. 2009), although they can extend to much higher frequencies (MacGillivray 2018), including at least 100 kHz (Tougaard et al. 2009). Deep and shallow-water conductor driving generate similar sound pressures; however, in deep water the pile is much longer so the ensonified area is greater (MacGillivray 2018). The radiated pile driving impulses vary in sound received levels as a function of range and azimuth, rise and decay times, pulse duration, and kurtosis (Amaral et al. 2020).

4.3. Drilling

Offshore drilling is a mechanical process where a wellbore is drilled into the seabed. Drilling can be used to explore for and extract hydrocarbons (oil and gas) from the ground. Drilling operations are typically conducted by jack-up drill rigs, semi-submersible drill rigs or drill ships collectively referred to as Mobile Offshore Drilling Units (MODUs). They are hull-based vessels equipped with drilling derricks which are either moored or under dynamic positioning whilst drilling.

4.3.1. Acoustic Emissions

Drilling sound usually exhibits tones below 2 kHz, with harmonics present to 10 kHz and can vary substantially between operations (Kyhn et al. 2014, Austin et al. 2018). These two studies are the most recent and detailed published studies on noise from offshore drilling operations, and they provide information about the current fleet of larger drilling units, as opposed to older, smaller units (e.g. Gales 1982, Greene 1987, Richardson et al. 1995), and supplement grey literature (e.g. MacDonnell 2017, Martin et al. 2019). Large offshore units are quite different in terms of their scale, operations involved, and sound emitted compared to smaller geotechnical drill rigs (Erbe and McPherson 2017).

The dynamic positioning of MODUs and drillships forms a significant component of the acoustic signature (Kyhn et al. 2014, MacDonnell 2017, Martin et al. 2019) and are often significantly louder than any drilling noise components. This is because thrusters generate high levels of thrust in poor flow conditions, resulting in significant propeller cavitation and consequently high underwater noise levels (Erbe et al. 2013).

4.4. Vessel Operations

The operation of motorised vessels involves numerous mechanical processes that create underwater sound as a by-product. These processes range from sound of the propeller, cavitation caused by propellers, flow noise from a vessel moving through water, engines and auxiliary machinery in the vessel hull. Sound emitted from vessels differs strongly, depending mainly on meteorological and oceanographic factors such as sea surface conditions and currents, type and state of propulsion system (including if the vessel is operating under dynamic positioning (DP)), vessel installed power, size, transit speed, and load (MacGillivray et al. 2018) (Figure 4).

Vessels, such as moored Floating Production Storage Offload (FPSO) facilities and Floating Liquid Natural Gas (FLNG) facilities, operate significant onboard machinery, and can use thrusters to assist in manoeuvring to assist offload or minimise weather impacts on operations (Erbe et al. 2013, Duncan 2014)

4.4.1. Acoustic Emissions

Figure 4 provides generic examples of frequency-dependent source levels for the most common vessel categories in 1/3-octave-bands (McPherson et al. 2019). The categories include vessel types relevant to the oil and gas industry such as tankers and Floating Production Storage and Offloading (FPSO) units. The only vessel in this example under DP is the FPSO. With an FPSO, processing equipment is mostly located on the deck with storage facilities below the deck. This setup, as well as the fact that FPSOs are usually double-hulled, helps insulate the marine environment from machinery noise on deck, however they still emit an obvious signature (Erbe et al. 2013).

Service, support, supply and construction vessels often are required to use DP to maintain position. The majority of measurement studies of vessels under DP are in grey literature, and associated with environmental approvals (e.g. Austin and Li 2016, MacDonnell 2017, Quijano and McPherson 2018, Martin et al. 2019), however there is some published literature (Kyhn et al. 2014).

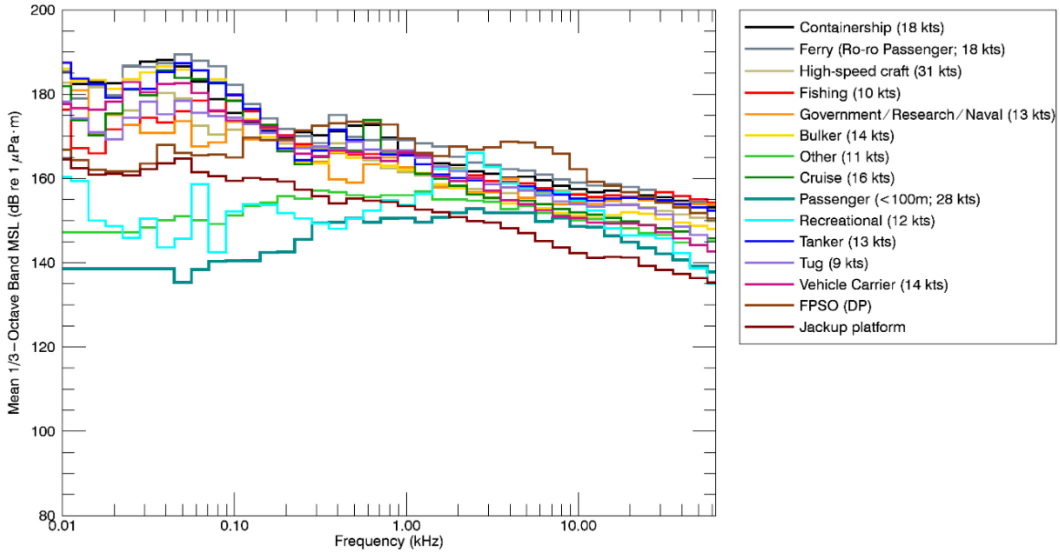

Figure 4. Example of frequency-dependent source levels for several categories of vessels in 1/3-octave-bands (source: McPherson et al. 2019).

5. Sound Perception

5.1. Hearing Sensitivity of Marine Animals

Marine animals only respond to acoustic signals they can detect. The sensitivity of an individual's auditory (i.e. hearing) system is described as a function of sound frequency. The lowest intensity of a sound at a particular frequency that an individual can hear describes its hearing threshold. The graphical representation of these thresholds over the range of frequencies that are audible to the individual is called its hearing curve or audiogram. Only a few individuals in a small number of marine species have been tested for their hearing sensitivity in all taxonomic groups of marine animals.

5.1.1. Marine Invertebrates

Some studies have been done on the sound perception of the following marine invertebrate groups:

- Plankton (including larval stages of larger marine invertebrates and fish);
- Bivalves (scallops, oysters) and decapods (crabs, prawns);
- Cephalopods (squid, octopus); and
- Other benthic invertebrate species.

Available literature suggests particle motion, rather than sound pressure, is a more important factor for marine invertebrate hearing. The sensory organs of marine invertebrates involved in receiving underwater sound can be classified into the following three groups (Budelmann 1992b):

- *Superficial receptor systems*: These receptors on the body surface are sensitive to water displacements; therefore; they mainly encode hydrodynamic cues;
- *Internal statocyst receptor systems*: Found in a wide range of aquatic invertebrates, these inertial gravity receptor systems may function as acoustic particle motion detectors and thus play a role in underwater hearing (Budelmann 1992b) or in substrate-borne vibrations (Cohen et al. 1953, Cohen 1955).
- *Chordotonal organs*: These proprioceptive receptors monitor joint movement, the direction of movement, and static position. These organs are sensitive to water oscillating in column surrounding them (Budelmann 1992a).

At the seafloor interface, marine invertebrates are subject to particle motion stimuli from several acoustic or acoustically induced waves. These include the particle motion associated with an impinging sound pressure wave in the water column (the incident, reflected, and transmitted portions), substrate acoustic waves, and interface waves (such as Scholte waves which are propagating at a water-sediment interface (Vinh 2013)). However, it is unclear which aspect(s) of these waves is/are most relevant to animals, either when the animals normally sense the environment or their physiological responses to loud sounds.

A few studies provide quantitative information on the sensitivity thresholds of marine invertebrates to sound. Electrophysiological studies measuring auditory evoked potentials (AEP) showed that cephalopods are capable of perceiving sound between 10 and 400 Hz (Packard et al. 1990, Parks et al. 2007b, Hu et al. 2009, Mooney et al. 2010, Hughes et al. 2014). In a behavioural study, Mooney et al. (2016) showed that squid (*Doryteuthis pealeii*) can perceive sound pressure of signals as low as 80 Hz and have their optimal hearing range between 200–400 Hz. Lovell et al. (2005) measured AEP responses in prawns (*Palaemon serratus*) between 100 Hz to 3 kHz, and Pye and Watson (2004) tested lobster (*Homarus americanus*) up to 5 kHz using the AEP technique. However, as pointed out by several authors (Ladich 2013, Popper et al. 2014, Hawkins et al. 2015, Sisneros et al. 2016), studies employing the AEP technique may not reflect the true sensitivity to acoustic stimuli as the studies fail to incorporate natural soundscapes and processing at higher cortical levels.

Packard et al. (1990) used a classical conditioning approach to test low-frequency hearing in cephalopods (*Sepia sp.*, *Octopus sp*., and *Loligo sp*.) and found the best sensitivities at 10 Hz and below. Other studies obtained perception thresholds (using reflex movements of antennae or legs as proxy) for underwater sound in species such as the brown shrimp (*C. crangon*) (Heinisch and Wiese 1987, Berghahn et al. 1995), hermit crab (*Pagurus bernhardus*) (Roberts et al. 2016), common littoral crab (*Carcinus maenas*) (Barth 1980), and northern prawn (*Pandalus borealis*) (Klages et al. 2002). These studies revealed these species are sensitive to acoustic or vibratory stimuli at frequencies below 400–500 Hz.

Moreover, detection of substrate-borne low-frequency vibration (<200 Hz) has been demonstrated to induce behavioural responses in some crustacean and bivalve species (Roberts et al. 2015, Roberts and Elliott 2017).

Most studies on marine invertebrates do not differentiate between pressure and particle motion. If conducted in tanks, the resulting thresholds and high-frequency ranges (e.g., Pye and Watson 2004, Lovell et al. 2005) may be artefacts, possibly resulting from acoustic interferences in the confines of the test environment (Sisneros et al. 2016, Carroll et al. 2017). The application of these experiment outcomes to impact assessments should be treated with caution due to the aspects regarding study design and representation of true hearing sensitivity (see above).

Mooney et al. (2010) quantify the acoustic sensitivity of the longfin squid (*Loligo pealeii*) using near-field acoustic and shaker-generated acceleration stimuli. Sound field pressure and particle motion components were measured from 30 to 10,000 Hz. Acceleration stimuli were measured from 20 to 1000 Hz. Their results suggest that squid detect the acceleration and particle motion components of a sound field up to frequencies of ~500 Hz.

Irrespective of the sensory modality for sound perception, marine invertebrates produce, detect, and respond to sound as shown in a review by Edmonds et al. (2016), thus indicating that these species are susceptible to effects from underwater sound. While research in this area is limited, the sensitivity of invertebrates to water borne particle motion and substrate vibration across a broad range of frequencies may potentially impact marine invertebrates through physical effects (Solé et al. 2017) and behaviour disruption (Solan et al. 2016).

5.1.2. Fishes

Although hearing ranges and sensitivities vary substantially between species (e.g., Ladich and Fay 2013), all fish species tested to date can hear (Dale et al. 2015). Fishes have developed two sensory mechanisms for detecting, localising, and interpreting underwater sounds and vibrations: the inner ear, which is tuned to sound detection, and the lateral line system, which allows them to detect vibration and water flow. Inter-specific variations in hearing range and sensitivity result from the different adaptations in these systems for perceiving sound pressure and particle motion information (Popper and Fay 2011).

The critical issue for understanding if an anthropogenic sound affects hearing is whether the sound is within the hearing (sound pressure) or detection (particle motion) frequency range of a fish and whether the sound is loud enough to be detected above its hearing threshold.

Sensitivity to sound pressure seems to be functionally correlated in fishes to the presence and absence of gas-filled chambers in the sound transduction system. These chambers enable fishes to detect sound pressure and to extend their hearing abilities to lower sound levels and higher frequencies (Ladich and Popper 2004, Braun and Grande 2008).

Based on their morphology, the Popper et al. (2014) classifications into three categories can be assigned to the following families or species of fish, common in Australian waters (see Figure 5 for hearing curves (‘audiograms’) of representatives of each group):

a. Fishes with swim bladders or other gas volumes, but whose hearing does not directly involve the swim bladder, e.g., snappers, emperors, groupers and rock cods (Lutjanids and Lethrinids such as *Pristipomoides spp*., *Lethrinus spp*., *Lutjanus spp*., and family Serranidae), and some species of tuna (*Thunnus sp*.) (Tavolga and Wodinsky 1963, Bertrand and Josse 2000, Higgs et al. 2006, Song et al. 2006, DoN US 2008, Braun and Grande 2008, Engineering-Environmental Management 2008, Caiger et al. 2012);

b. Fishes whose hearing does directly involve a swim bladder or other gas volume e.g., family Clupeidae (herrings, sardines, pilchards and shads), family Gadidae (true cods such as whiting), and potentially some nearshore/reef species relevant to tropical Australia, including some Pomacentridae (damsel fishes and clown fishes), some Holocentridae (soldierfishes and squirrelfishes) and some Haemulidae (grunters and sweetlips) (Nedwell et al. 2004, Braun and Grande 2008, Popper et al. 2014); and

c. Fishes without a swim bladder (e.g., mackerel, *Scomberomorus spp*., and sharks, including whale sharks, *Rhincodon typus*) (Casper et al. 2012, Popper et al. 2014, Carroll et al. 2017).

Most fishes are primarily sensitive to particle motion effects, while fishes with hearing that involves the swim bladder are also sensitive to sound pressure (Popper and Hawkins 2019, Popper et al. 2019). The most relevant metric for perceiving underwater sound for most fish species is, therefore, particle motion. However, with the exception of few species (Popper and Fay 2011, Popper et al. 2014) (Figure 5), there is an almost complete lack of relevant data on particle motion sensitivity in fishes (Popper and Hawkins 2018).

Most fish species investigated for sound pressure sensitivity can detect sounds from below 50 Hz up to 500–1500 Hz. A smaller number of species can detect sounds to over 3 kHz, while a very few species can detect sounds to well over 100 kHz; Mann et al. (1997, 1998) showed that the American shad (*Alosa sapidissima*, order: clupeiforms) can detect sounds up to 180 kHz. These species have two pairs of air bubbles in their inner ears that aid in sound detection. The authors subsequently investigated ultrasound hearing in other clupeid species and found that ultrasound detection may be limited to one subfamily of clupeiforms, the Alosinae (Mann et al. 2001). The hearing range in other clupeids such as the herring (*Clupea harengus*), however, is limited between 100–5000 Hz (Mann et al. 2005).

Ideally, auditory experiments in fishes should be conducted under conditions reflecting the acoustic conditions experienced by the animals in a free-field situation. For example, Dale et al. (2015) measured the auditory sensitivity of free-swimming Pacific bluefin tuna (*Thunnus orientalis*) in a tank and reported both sound components. Moreover, their approach to conducting a hearing test in swimming animals also takes the flow-noise created by the animals' own movement into account.

Elasmobranchs (sharks, rays, and skates) have no swim bladder or other gas bubble associated with their ears (category III), but they can detect and respond to sound (reviewed in Myrberg 1978, 1990, 2001, Casper and Mann 2009). Their range of best hearing sensitivity extends from below 50 Hz to over 500 Hz with relatively poor hearing sensitivity. While it is unclear what role sound plays in their life these species are less likely to be negatively affected by intense underwater sound.

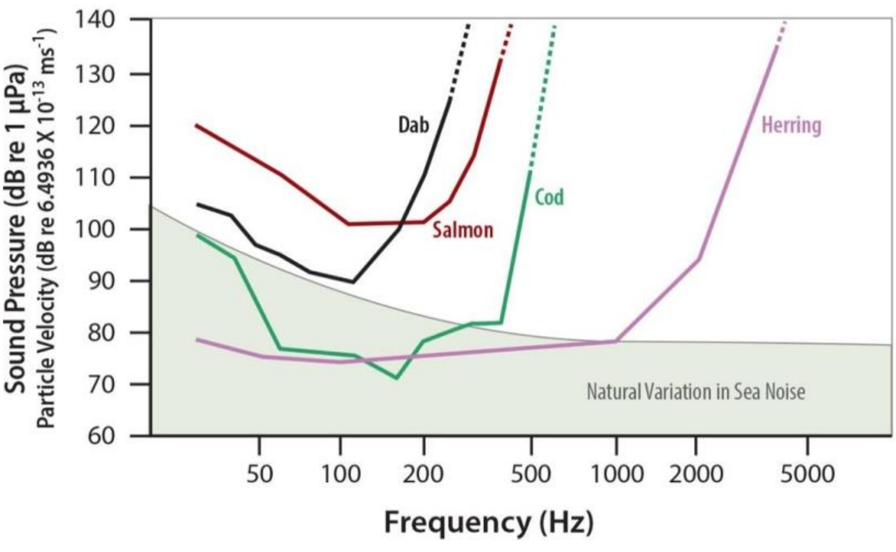

Figure 5. Fish audiograms obtained under open sea, free-field conditions; species representing different categories as classified by Popper et al. (2014) (source: Popper et al. 2019). Salmon (*Salmo salar*) have a swim bladder that does appear to play a role in hearing (category I), cod (*Gadus morhua*) and herring (*Clupea harengus*) have special structures mechanically linking the swim bladder to the ear (category II) and dab (*Limanda limanda*) are bottom-living fish with no swim bladder (category III).

5.1.3. Sea Turtles

In-air and underwater hearing studies in sea turtles indicate that all species tested have poor hearing sensitivity. Ridgway et al. (1969) measured cochlear potentials from green sea turtles (*Chelonia mydas*) in response to in-air acoustic stimuli and, while not measuring absolute hearing thresholds, detected responses over a limited frequency range (200–700 Hz) with best sensitivity at 400 Hz. Piniak et al. (2016) found that green turtles have maximum underwater sensitivity between 200 and 400 Hz.

Bartol et al. (1999) used vibratory stimuli to measure the hearing sensitivity of loggerhead turtles (*Caretta caretta*). The results show that this species has an in-air hearing sensitivity of up 1 kHz for tones and clicks. Underwater hearing sensitivity has been measured in the loggerhead turtle (Martin et al. 2012), demonstrating highest sensitivity at around 500 Hz (Willis 2016). Yudhana et al. (2010) measured auditory brainstem responses from two hawksbill turtles (*Eretmochelys imbricate)* in Malaysia and found that peak frequency sensitivity occurred at 457 Hz in one turtle and at 508 Hz in the other.

Ketten and Bartol (2005) conducted a series of electrophysiological studies establishing the hearing thresholds in three sea turtles species and documented age and species variations in response to underwater sound. Their data show that juvenile green turtles have a slightly broader hearing range (100–800 Hz; best sensitivity 600–700 Hz) than the range of sub-adults (100–500 Hz). Kemp's Ridley's sea turtles (*Lepidochelys kempi*) had a more restricted range (100–500 Hz) with most sensitive hearing at 100–200 Hz. Two-year old loggerhead turtles (*Dermochelys coriacea*) responded to sounds ranging from 100–700 Hz, while the three-year old animals responded to sounds between 100–400 Hz.

A small number of studies researching the effect of seismic noise on sea turtles focused on behavioural responses. Turtles avoid low-frequency sounds (Lenhardt 1994) and sounds from an airgun (O'Hara and Wilcox 1990), but these reports did not report received sound levels. Moein et al. (1995) found that penned loggerhead turtles initially reacted to seismic airgun stimuli but then showed little or no response to the sound (i.e., they likely habituated to it). Caged green and loggerhead sea turtles increased their swimming activity in response to an approaching airgun when the received SPL was above 166 dB re 1 μPa, and they behaved erratically when the received SPL was ~175 dB re 1 μPa (McCauley et al. 2000a).

5.1.4. Marine Mammals

This taxonomic group comprises all aquatic or semi-aquatic mammalian species, including cetaceans, pinnipeds, sirenian, mustelids and the polar bears. Current data and predictions on hearing sensibility show that marine mammal species differ in their hearing capabilities, in absolute hearing sensitivity, as well as their frequency band of hearing (Richardson et al. 1995, Wartzok and Ketten 1999, Southall et al. 2007, Southall et al. 2019). While hearing measurements are available for an increasing number of species, mainly based on captive animal studies, direct measurements of many odontocetes and all mysticetes do not exist. As a result, hearing ranges for many odontocetes are grouped with similar species into functional hearing groups, and predictions for mysticetes are based on other methods, such as anatomical studies and modelling (Houser et al. 2001, Parks et al. 2007b, Tubelli et al. 2012, Cranford and Krysl 2015), vocalisations (see reviews in Richardson et al. 1995, Wartzok and Ketten 1999, Au and Hastings 2008b, Southall et al. 2019), taxonomy, and behavioural responses to sound (Dahlheim and Ljungblad 1990, Nowacek et al. 2007, Ellison et al. 2012).

5.1.4.1. Functional Hearing Groups

To better reflect the auditory similarities between phylogenetically closely related species, but also significant differences between species groups among the marine mammals, Southall et al. (2007) assigned the extant marine mammal species to functional hearing groups based on their hearing capabilities and sound production. This division into broad categories was intended to provide a realistic number of categories for which individual noise exposure criteria were developed. These groups were revised by NMFS (2018) and most recently by Southall et al. (2019). The categorisation as such has proven to be a scientifically justified and useful approach in developing auditory weighting functions and deriving noise exposure criteria for marine mammals. Based on the most recent information about similarities in hearing sensitivity between marine mammal species, Southall et al. (2019) proposed an updated new nomenclature and classification for the marine mammal functional hearing groups (Table 2).

Table 2. Functional marine mammal hearing groups and their generalised hearing range (Southall et al. 2019) and nomenclature used in the most recent underwater noise exposure regulation (NMFS 2018); N/A – not applicable, n.d. – no data provided.

Hearing group	Previously used classification and nomenclature (NMFS 2018)	Generalised hearing range*
Low-frequency (LF) cetaceans (mysticetes or baleen whales)	Low-frequency (LF) cetaceans (mysticetes or baleen whales)	7 Hz to 34 kHz
High-frequency (HF) cetaceans (other odontocetes)	Mid-frequency (MF) cetaceans (odontocetes: delphinids, beaked whales)	40 Hz to 160 kHz
Very-high frequency (VHF) cetaceans	N/A	300 Hz to 160 kHz
Phocid carnivores (PCW) (in water)	Phocid pinnipeds (PW) (underwater)	<75 Hz to 100 kHz
Phocid carnivores (PCA) (in air)	N/A	n.d.
Other marine carnivores (OCW) (in water)	Otariid pinnipeds (OW) (underwater)	100 Hz to 55 kHz
Other marine carnivores (OCA) (in air)	N/A	n.d.
Sirenia (SI)	N/A	<250 Hz to 72 kHz

* The generalised hearing range for all species within a group. Individual and species-specific hearing will vary.

The following sections provide an overview of hearing studies on marine mammals conducted following the comprehensive review by Southall et al. (2007).

5.1.4.1.1. Low-frequency (LF) Cetaceans

This functional hearing group comprises all baleen whale species (mysticetes). To this date, there has been no direct measurement of hearing sensitivity in any of these species. Instead, vocalisation frequency ranges have been used as a proxy to determine their hearing range. However, Houser et al. (2017) noted that vocalisation frequencies do not necessarily represent the full extent of their frequency range of best hearing and therefore vocalisation frequencies are a poor predictor of best hearing thresholds.

In the complete absence of direct data on auditory sensitivity in any baleen whale species, behavioural reactions provide some insight into the sound perception capabilities and sensitivities of mysticetes. Nowacek et al. (2007, 2015) reviewed previous studies and published new data on behavioural reactions of mysticetes . However, behavioural reactions are strongly context specific (Ellison et al. 2012) and are consequently also of limited use in delineating hearing ranges or even predicting hearing sensitivity.

The existing data so far suggest that some species (e.g., blue whales, *Balaenoptera musculus,* and fin whales, *Balaenoptera physalus*) have better low-frequency sensitivity while others (e.g., humpback whales, *Megaptera novaeangliae* and minke whales, *Balaenoperta acutorostrata*) have better sensitivity to higher frequencies.

In another approach, anatomical data have been used to predict hearing ranges in mysticetes (e.g., Parks et al. 2007b, Manoussaki et al. 2008). Most recently, functional models were developed focussing on different components of the hearing system (Tubelli et al. 2012, Ketten and Mountain 2014, Cranford and Krysl 2015). In combination with anatomical data on the hearing system, the audible frequency range of mysticetes—collectively treated as a single functional hearing group—is approximately between 7 Hz and 34 kHz (Southall et al. 2019).

5.1.4.1.2. High-frequency (HF) Cetaceans

Based on the frequency range of their vocal emissions as well as their known hearing ranges, most dolphin species, all beaked whale species, and sperm whales belong to this functional hearing group.

Following the initial review of existing information on marine mammal hearing by (Southall et al. 2007) hearing sensitivity has been directly measured recently for a number of species within this group; this includes several dolphin species (Pacific bottlenose dolphin (*Tursiops truncatus gilli*) (Houser et al. 2008), white-beaked dolphin (*Lagenorhynchus albirostris*) (Nachtigall et al. 2008), long-finned pilot whale (*Globicephala melas*) (Pacini et al. 2010), short-finned pilot whales (*Globicephala macrorhynchus*) (Schlundt et al. 2011), Indo-Pacific humpback dolphin (*Sousa chinensis*) (Li et al. 2012), beluga (*Delphinapterus leucas*) (Castellote et al. 2014), and killer whale (*Orcinus orca*) (Branstetter et al. 2017)) and two beaked whale species (Gervais' beaked whale (*Mesoplodon europaeus*) (Finneran et al. 2009), and Blainville's beaked whale (*Mesoplodon densirostris*) (Pacini et al. 2011)).

The white-beaked dolphins showed hearing sensitivity ranging from 16 to 181 kHz and showed the typical U-shaped curve for odontocetes. The thresholds for both animals tested demonstrated the most sensitive high-frequency hearing of any known dolphin and indicates that this species is as sensitive as the harbour porpoise. The long-finned pilot whale had relatively poor high-frequency hearing compared with other odontocete species and a region of best hearing between 11.2 and 50 kHz. Hearing in the killer whales was assessed as being generally similar to other delphinids, with the lowest threshold (49 dB re 1 µPa) at 34 kHz and a functional hearing range between 5 and 81 kHz.

The best hearing in beaked whales was determined at 40–60 kHz, with an upper functional hearing limit of ~80 kHz. There were indications for reduced overall hearing sensitivity in beaked whales as compared to other HF cetacean species, e.g., bottlenose dolphins.

Most of the audiograms measured in mid-frequency cetaceans follow the same general 'mammalian' U-shape and have a nominal hearing range starting at ~40 Hz up to 160 kHz. These frequencies were used as the lower and upper cut-off frequencies for the functional hearing limits by NMFS (2018).

5.1.4.1.3. Very high-frequency (VHF) Cetaceans

The VHF cetaceans are a group comprising porpoises [finless porpoise (*Neophocaena phocaenoides*), harbour porpoise (*Phocoena phocoena*), Vaquita (*Phocoena sinus*), Burmeister's porpoise (*Phocoena spinipinnis*), spectacled porpoise (*Phocoena dioptrica*) and Dall's porpoise (*Phocoenoides dalli*)]; river dolphins [La Plata river dolphin (Franciscana, *Pontoporia blainvillei*), Yangtze river dolphin (Baiji, *Lipotes vexillifer*, functionally extinct (Turvey et al. 2007)), Amazon river dolphin (Boto, *Inia geoffrensis*) and South Asian river dolphin (*Platanista gangetica*)]; Kogia species [Pygmy sperm whale (*Kogia breviceps*), Dwarf sperm whale (*Kogia sima*)]; Cephalorhynchus species [Commerson's dolphin (*Cephalorhynchus commersonii*), Chilean dolphin (*Cephalorhynchus eutropia*), Heaviside's dolphin (*Cephalorhynchus heavisidii*) and Hector's dolphin (*Cephalorhynchus hectori*)].

New information on the capabilities of the hearing system has been published for harbour porpoises (Kastelein et al. 2010, Kastelein et al. 2015c, Ruser et al. 2016, Kastelein et al. 2017a) and the Yangtze river dolphin (Popov et al. 2011). The audiograms measured in these species show the general 'mammalian' U-shape with a nominal hearing range between 300 Hz and 160 kHz that were subsequently used as lower and upper cut-off frequencies for the functional hearing limits for this animal group.

5.1.4.1.4. Phocid Carnivores in Water (PCW) and in Air (PCA)

Phocids comprise all 'true' seal species; their auditory system has special anatomical features (Wartzok and Ketten 1999, Reichmuth et al. 2013) that have led to the description of a unique 'phocid ear type' for this group (Nummela 2008). Reichmuth (2008) reviewed the available information on hearing in marine carnivores. Hearing sensitivity was investigated in comparative studies between phocid and otariid seals (Reichmuth et al. 2013, Cunningham and Reichmuth 2016), studies on specific aspects of underwater hearing in pinnipeds (Hemilä et al. 2006, Bowles et al. 2010, Cunningham et al. 2014, Stansbury et al. 2015) or species-specific studies on hearing sensitivity

(Kastelein et al. 2009, Reichmuth and Southall 2012, Sills et al. 2014, 2015). The results indicate that underwater hearing sensitivity in phocid seals extends from 75 Hz to 100 kHz (Southall et al. 2019).

5.1.4.1.5. Other Marine Carnivores in Water (OCW) and in Air (OCA)

This functional hearing group is comprised of otariids and odobenids as well as ursiids and mustelids.

Otariids include all eared seals (fur seals and sea lions). The walrus (*Odobenus rosmarus*) is an arctic species and the only extant odobenid species. Even though odobenids share the anatomical adaptations found in phocids to some extent, they are more similar to otariids in their hearing capabilities.

Besides the review by Reichmuth (2008) and comparative studies (Reichmuth et al. 2013, Cunningham and Reichmuth 2016), only two publications (Mulsow et al. 2012, Reichmuth and Southall 2012) provided new data on the underwater hearing of an otariid species, the California sea lions (*Zalophus californianus*). Based on all existing information, the otariid hearing limits are estimated to be 100 Hz to 55 kHz for underwater sound. There are no new data available for odobenids. With regard to the auditory parameters applied for deriving a weighting function and noise exposure criteria, the hearing limits defined for otariids were applied to walruses.

Hearing threshold measurements in polar bears (*Ursus maritimus*) have only been conducted in air (Nachtigall et al. 2007, Owen and Bowles 2011). These studies revealed auditory sensitivity to in-air sound stimuli up to ~20 kHz.

Ghoul and Reichmuth (2014) measured the hearing sensitivity of an individual sea otter (*Enhydra lutris*) in air and underwater. Their results show the aerial hearing sensitivity of the sea otter resembled that of sea lions; their best sensitivity was −1 dB re 20 µPa at 8 kHz. Under water, their hearing sensitivity was significantly reduced when compared to sea lions and other pinniped species, demonstrating that sea otter hearing is primarily adapted to receive airborne sounds.

5.1.4.1.6. Sirenia (SI)

This functional hearing group comprises three species of manatees (*Trichechus spp.*), which occupy warm latitudes of the coastal Atlantic Ocean and associated rivers, and the dugong (*Dugong dugon*), which inhabits the coastlines of the Indian and Pacific Oceans.

Behavioural and electrophysiological hearing data for manatees indicate some similarities to HF cetaceans and phocid pinnipeds (Southall et al. 2019). Assessments of Florida manatee (*Trichechus manatus latirostris*) hearing sensitivity indicate best hearing sensitivity between 8 and 32 kHz (Gerstein et al. 1999, Gaspard et al. 2012). Combined data suggest that sirenian have functional hearing between approximately 250 Hz and 80 kHz (Southall et al. 2019). However, extended hearing sensitivity has been measured for frequencies up to 90.5 kHz (Gaspard et al. 2012), suggesting that ultrasonic frequencies could play an important role in their lives.

5.1.4.2. Auditory Frequency Weighting Functions

The potential for anthropogenic sounds to impact marine mammals is largely dependent on whether the sound occurs at frequencies that an animal can hear well, unless the sound pressure level is so high that it can cause physical tissue damage regardless of frequency. Auditory (frequency) weighting functions reflect an animal’s ability to hear a sound (Nedwell and Turnpenny 1998, Nedwell et al. 2007). Houser et al (2017) provide an example illustrating the effect of applying a weighting function to a (hypothetical) sound (Figure 6).

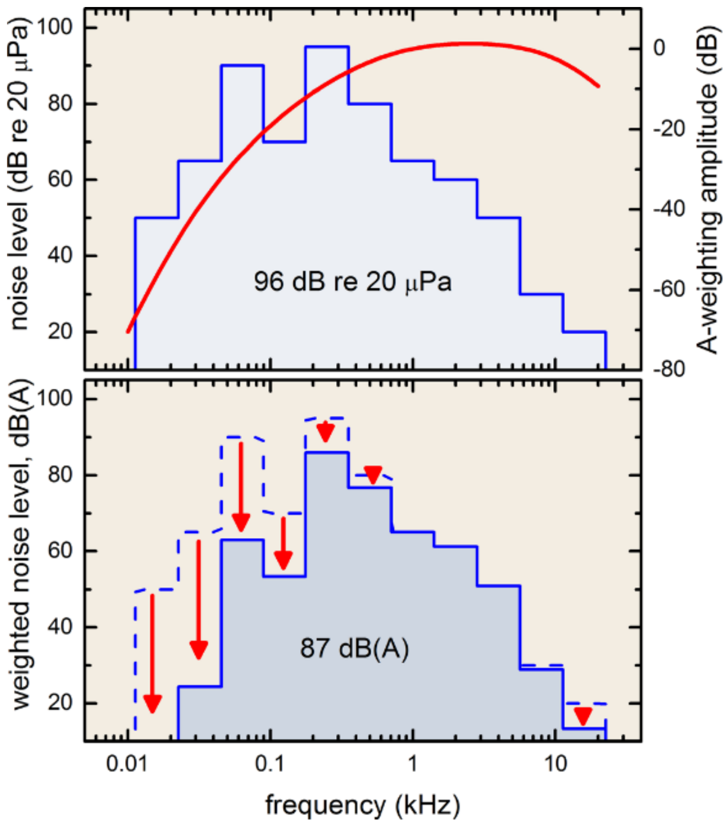

Figure 6. Application of an auditory weighting function. Blue line shows a hypothetical, octave-band sound pressure spectrum in air, with a total sound pressure level (integrated over all octave-bands) of 96 dB re 20 µPa (This example uses in air-noise levels; therefore, a different reference pressure (20 µPa) applies. The principle is identical to underwater sound where a reference pressure of 1 µPa applies). (Top) Red line shows the human A-weighting function amplitude (A-weighting applies only to human hearing). (Bottom) To determine the weighted exposure level, the A-weighting amplitude at each frequency is added to the sound pressure level at each frequency (red arrows). The weighted spectrum has lower amplitude at the frequencies where the A-weighting function amplitudes are negative. The values from 1–4 kHz do not change substantially, because the weighting function is flat (i.e., the weights are near zero). The weighted SPL is calculated by integrating the weighted spectrum across all octave-bands; the result is 87 dBA, meaning a sound pressure level of 87 dB re 20 µPa after applying the human A-weighting function (Source: Houser et al. 2017).

Auditory weighting functions have been proposed for marine mammals, specifically associated with PTS thresholds expressed in metrics that consider what is known about marine mammal hearing (e.g., SEL (L_E)) (Southall et al. 2007, Erbe et al. 2016a, Finneran 2016). Marine mammal auditory weighting functions published by Finneran (2016) are included in the NMFS (2018) Technical Guidance for use in conjunction with corresponding PTS (injury) onset acoustic criteria and Southall et al. (2019). Figure 7 shows the resulting frequency-weighting curves for marine mammals.

Applying marine mammal auditory weighting functions emphasizes the importance of making measurements and characterizing sound sources in terms of their overlap with biologically-important frequencies (e.g., frequencies of environmental signals, communication, or the detection of predators or prey), and not only the frequencies of interest or concern for the sound-producing activity such as a vessel (i.e., context of sound source; NMFS 2018).

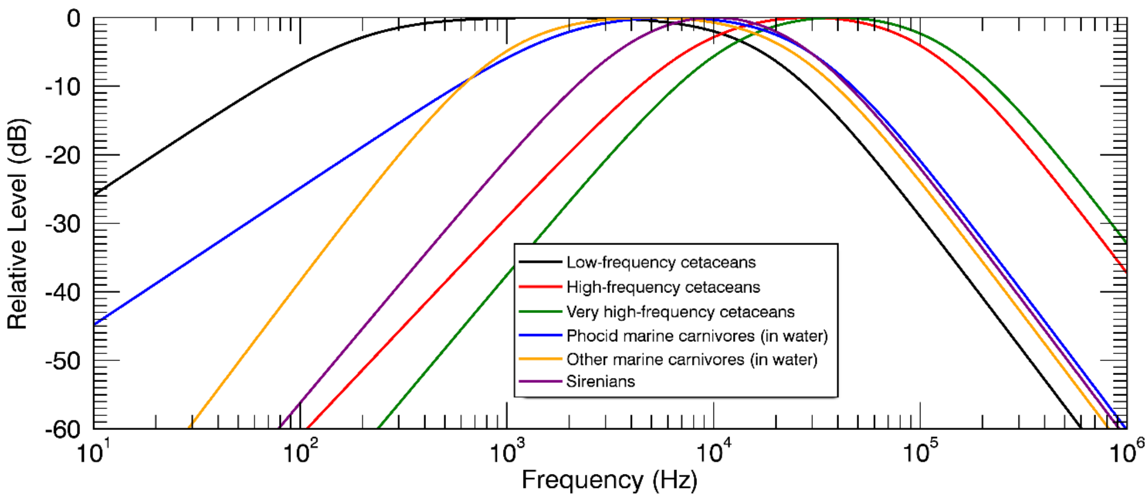

Figure 7. Auditory weighting functions for functional marine mammal hearing groups as proposed by NMFS (2018) and, with altered nomenclature (see Table 2), by Southall et al. (2019).

5.2. Noise Criteria and Rationale

To assess the potential impacts of noise exposure, criteria must first be established for which sound levels may be expected to negatively impact animals.

For marine mammals, NMFS issued a Technical Guidance document that provides acoustic thresholds for the onset of temporary threshold shift (TTS) and permanent threshold shift (PTS) in marine mammal hearing for all sound sources (NMFS 2018). NMFS also provided guidance on the use of weighting functions when applying injury criteria. The NMFS Guidance recommends applying a dual criterion for assessing injurious exposures, including an unweighted (flat) peak sound pressure level metric PK (L_{pk}) and a sound exposure level SEL_{cum} ($L_{E,24h}$) metric with frequency weighting. Both acoustic criteria and weighting function application are different for the marine mammal functional hearing groups.

Southall et al. (2019) published an updated set of criteria for onset of TTS and PTS in marine mammals. While the authors propose a new nomenclature and classification for the marine mammal functional hearing groups[1], the proposed thresholds and weighting functions for exposure to underwater sound do not differ in effect from those proposed by NMFS (2018).

Injurious effects caused by rapid pressure changes within the body are called 'barotrauma' (Stephenson et al. 2010, Halvorsen et al. 2011, 2012b). Popper et al. (2014) developed a set of criteria for fishes that are based on onset levels for barotrauma injury. These criteria are supported by data from Casper et al. (2013), who showed that less acoustic energy is required for the onset of barotrauma in fishes than for the onset of hair cell damage (the 'typical' cause for hearing impairment in mammals). Injuries include direct mortality, non-recoverable injury, and recoverable injury including TTS (Hawkins and Popper 2017). Criteria were chosen for all types of acoustic signals based on results from exposures to impulsive pile driving. This represents a conservative approach, as impulsive noise has a higher potential to cause deleterious effects than non-impulsive sounds. The guidelines suggested by Popper et al. (2014) then separated marine fishes into four classes according to available data on hearing sensitivity and onset of injury in relation to their developmental stage (e.g., eggs and larvae versus adult fishes) and the presence of morphological adaptations to their hearing system. The logic for choosing this indicator (injury), the baseline data (pile driving) and classification (animal groups) is reasonable and supported by the best available knowledge.

[1] The new hearing groups proposed by Southall et al. (2019) have not yet been adopted by NMFS.

5.2.1. Definitions of Sound Type

Underwater noise exposure criteria for marine fauna differ substantially for impulsive and non-impulsive sounds. However, there are some discrepancies in defining the impulsiveness of sound and, accordingly, classifying sounds in either of sound-type category.

A technical definition of impulsive noise is given by the International Standardisation Organisation, ISO: “Impulsive noise (ISO 2923:1996(en), 3.8): Noise of less than one-second duration which occurs as an isolated event or as one of a series of events with a repetition rate of fewer than 15 times per second. The presence of impulsive noise shall be determined by obtaining the difference between the equivalent continuous sound pressure level measured with time weighting I and F. If the difference is more than 2 dB, the presence of impulsive noise may be assumed.” (1996). Harris (1998) proposed a distinction between impulsive and non-impulsive sounds based on the different time constant used in sound level meters for measuring impulses (time constant: 35 ms) and non-impulsive sounds (time constants: 125 ms and 1,000 ms). A ≥3 dB difference in measurements between these settings constitutes an impulse while non-pulses sounds are characterised by <3 dB difference.

Based on these definitions, classifying most sounds into the two sound types seems straight forward and non-controversial. Problems arise with classifying commercial sonars and echosounders. Also, impulsive and non-impulsive sounds (Section 3.2) are typically determined based on their acoustic characteristics measured at the sound source. For distant receivers, however, pulsed sounds may lack the characteristics described above because long-distance underwater sound propagation attenuates at high frequencies more than at low frequencies (e.g., Martin et al. 2017). Over distance, this may change the structure of an impulsive sound to a non-impulsive sound, which would have regulatory implications as different thresholds apply to both types of sound under most jurisdictions.

5.2.2. Marine Invertebrates

5.2.2.1. Plankton

To assess impacts to plankton, there are only a few studies to base noise exposure threshold criteria on. Popper et al. (2014) published exposure guidelines for fish eggs and larvae that are based on exposure experiments using impact pile driving signals as test stimuli. Popper et al. (2014) proposed a threshold for mortality of fish eggs and larvae of >207 dB re 1 µPa PK (see Tables 3 and 4), which the authors note is likely to be conservative. There is no other official or widely accepted threshold for the onset of noise-induced effects for any planktonic species.

Results presented in Day et al. (2016b) for embryonic lobsters and Fields et al. (2019) for copepods align with those presented in Popper et al. (2014), which is that mortality and sub-lethal injury are limited to within tens of metres of seismic sources.

Other research has indicated the potential for effects at longer range: McCauley et al. (2017) reported changes in abundance and mortality in zooplankton over a range of 1.2 km after exposure to airgun sounds generated with a single airgun (150 in^3). Based on these results, a sound level of 178 dB re 1 µPa PK-PK in the water column has been proposed which could inform a highly conservative impact assessment but should not be regarded as an authoritative threshold. Fields et al. (2019) noted that it was difficult to reconcile the high mortality reported by McCauley et al. (2017) with the low mortalities reported in the previous body of earlier research and their experiment. They recommended further research into whether it is the sound pulse itself (i.e. the energy, peak pressures, or particle acceleration) or other factors not related to the sound impulse that might cause higher mortality.

5.2.2.2. Bivalves and Decapods

There are no guidelines or criteria regulating the underwater noise exposure of bivalves and decapods. There is not enough information to establish similar criteria and thresholds as was done for marine mammals and fish. Including recent research such as Day et al. (2016a), current literature does not clearly define an appropriate metric or identify relevant levels (pressure or particle motion) for an assessment. This includes considering what particle motion levels lead to a behavioural response or to mortality.

Therefore, at this stage, authoritative thresholds to inform an impact assessment do not exist. However, levels can be determined for pressure metrics presented in the literature to assist impact assessment: Peak-to-peak pressure levels (PK-PK; $L_{pk\text{-}pk}$) and particle acceleration at the seafloor can be used to help assess effects of noise on bivalves and decapods through comparing to results in Day et al. (2016a), (2019), (2016b), (2017), and Payne et al. (2008) (see Section 7.1.2 for more detail).

5.2.2.3. Cephalopods

There are no guidelines or criteria regulating the underwater noise exposure of cephalopods such as squid. In the absence of regulatory guidance, documented levels for onset of aversive behavioural reactions (Fewtrell and McCauley 2012) have been proposed for impulsive sound sources, such as seismic airguns (see detailed information in Section 7.1.3.1).

As with bivalves and decapods, there is not enough information to establish criteria and thresholds similar to those developed for marine mammals and fish. Moreover, current literature does not clearly define an appropriate metric or identify relevant levels (pressure or particle motion) for an assessment. This includes considering what particle motion levels lead to a behavioural response or to mortality.

5.2.2.4. Other Benthic Invertebrate Species

There are no guidelines or criteria regulating the underwater noise exposure of benthic species. As with the other marine invertebrate groups, there is not enough information to establish criteria and thresholds similar to those developed for marine mammals and fish. In the absence of authoritative thresholds, Heyward et al. (2018) reported a sound level of 226 dB re 1 µPa PK (L_{pk}) as a safe level of exposure for sponges and corals.

5.2.3. Fish

The Working Group on the Effects of Sound on Fish and Turtles undertook a review of experimental findings of sound effects on fishes (Popper et al. 2014). Previously, strong emphasis in assessing the effects of sounds had been placed on the hearing sensitivity of fishes. However, although hearing has to be taken into account, other effects also have to be considered (Hawkins et al. 2020). Popper et al. (2014) presented quantitative sound exposure guidelines for different groups of species and sound sources (Tables 3 and 4), for three types of immediate effects:

- Mortality, including injury leading to death;
- Recoverable injury, including injuries unlikely to result in mortality, such as hair cell damage and minor haematoma; and
- TTS.

The onset level of behavioural responses in fishes varies greatly between and within species, including variables such as fish age and size, the behavioural and social context during exposure, and the motivation of the fishes. Existing data on behavioural responses do not provide a clear dose-response relationship. Consequently, it is currently impossible to determine single value thresholds for the onset of behavioural reactions.

In the absence of any qualitative scientific information on behavioural responses of fish and auditory masking, applying relative risk categories such as those proposed by Popper et al. (2014) seem most reasonable to apply rather than specific sound level thresholds.

The SEL metric integrates noise intensity over some period of exposure. Because the period of integration for regulatory assessments is not well defined for sounds that do not have a clear start or end time, and for very long-lasting exposures, an exposure evaluation time must be defined. Southall et al. (2007) defines the exposure evaluation time as the greater of 24 h or the duration of the activity. Popper et al. (2014) recommend a standard period of the duration of the activity; however, the publication also includes caveats about considering the actual exposure times if fish move.

As discussed in Popper (2018), fish are mobile and some move over large distances. Popper suggests that it is reasonable to assume that if the sound of a seismic source becomes too loud, the fish will move away from the source because they are able to determine the direction of a sound source. If the fish moves away, the amount of energy to which it is exposed is likely to be one or a few seismic pulses, and these would not likely be loud enough to result in any effect because the fish would move away at a much lower level signal than could cause harm. Data on TTS for fish are limited to one study that examined recovery from seismic airgun impulses on caged fish (Popper et al. (2005b). Popper (2018) has since stated that if this study had been conducted on wild, free-swimming fish instead of caged ones, there would have been no effect whatsoever because they were likely to have moved away from the source as it approached them.

Table 3. Noise exposure criteria for pile driving and seismic noise exposure for fish, fish eggs and larvae, adapted from Popper et al. (2014).

Type of animal	**Mortality and Potential mortal injury**	**Impairment**			**Behaviour**
		Recoverable injury	TTS	Masking	
Fish: No swim bladder (particle motion detection)	> 219 dB SEL_{24h} or > 213 dB PK	> 216 dB SEL_{24h} or > 213 dB PK	>> 186 dB SEL_{24h}	Pile driving: (N) Moderate (I, F) Low Seismic: (N, I, F) Low	(N) High (I) Moderate (F) Low
Fish: Swim bladder not involved in hearing (particle motion detection)	210 dB SEL_{24h} or > 207 dB PK	203 dB SEL_{24h} or > 207 dB PK	>> 186 dB SEL_{24h}	Pile driving: (N) Moderate (I, F) Low Seismic: (N, I, F) Low	(N) High (I) Moderate (F) Low
Fish: Swim bladder involved in hearing (primarily pressure detection)	207 dB SEL_{24h} or > 207 dB PK	203 dB SEL_{24h} or > 207 dB PK	186 dB SEL_{24h}	Pile driving: (N, I) High (F) Moderate Seismic: (N, I) Low (F) Moderate	(N, I) High (F) Moderate
Fish eggs and fish larvae	> 210 dB SEL_{24h} or > 207 dB PK	(N) Moderate (I) Low (F) Low	(N) Moderate (I) Low (F) Low	Pile driving: (N) Moderate (I, F) Low Seismic: (N, I, F) Low	(N) Moderate (I, F) Low

Peak sound pressure level dB re 1 μPa; SEL_{24h} dB re 1μPa^2·s.
All criteria are presented as sound pressure even for fish without swim bladders since no data for particle motion exist.
Relative risk (high, moderate, low) is given for animals at three distances from the source defined in relative terms as near (N, tens of meters), intermediate (I, hundreds of meters), and far (F, thousands of meters).

Table 4. Noise exposure criteria for shipping and other non-impulsive noise exposure for fish, fish eggs and larvae, adapted from Popper et al. (2014).

Type of animal	Mortality and Potential mortal injury	Impairment			Behaviour
		Recoverable injury	TTS	Masking	
Fish: No swim bladder (particle motion detection)	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) Moderate (I) Low (F) Low	(N) High (I) High (F) Moderate	(N) Moderate (I) Moderate (F) Low
Fish: Swim bladder not involved in hearing (particle motion detection)	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) Moderate (I) Low (F) Low	(N) High (I) High (F) Moderate	(N) Moderate (I) Moderate (F) Low
Fish: Swim bladder involved in hearing (primarily pressure detection)	(N) Low (I) Low (F) Low	170 dB for 48 h	158 dB for 12 h	(N) High (I) High (F) High	(N) High (I) Moderate (F) Low
Fish eggs and fish larvae	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) High (I) Moderate (F) Low	(N) Moderate (I) Moderate (F) Low

All criteria are presented as sound pressure level (SPL) even for fish without swim bladders since no data for particle motion exist. Relative risk (high, moderate, low) is given for animals at three distances from the source defined in relative terms as near (N, tens of meters), intermediate (I, hundreds of meters), and far (F, thousands of meters).

5.2.4. Sea Turtles

There is a paucity of data regarding responses of turtles to acoustic exposure, and no studies of hearing loss due to exposure to loud sounds. Popper et al. (2014) suggested thresholds for onset of mortal injury (including PTS) and mortality for sea turtles and, in absence of taxon-specific information, adopted the levels for fish that do not hear well (suggesting that this likely would be conservative for sea turtles).

Finneran et al. (2017) presented revised thresholds for sea turtle injury and hearing impairment (TTS and PTS). Their rationale is that sea turtles have best sensitivity at low frequencies and are known to have poor auditory sensitivity (Bartol & Ketten, 2006; Dow Piniak et al. 2012; Martin et al. 2012). Accordingly, TTS and PTS thresholds for turtles are likely more similar to those of fishes than to marine mammals (Popper et al. 2014).

McCauley et al. (2000b) observed the behavioural response of caged sea turtles—green (*Chelonia mydas*) and loggerhead (*Caretta carett*a)—to an approaching seismic airgun. For received levels above 166 dB re 1 µPa (SPL), the sea turtles increased their swimming activity and above 175 dB re 1 µPa they began to behave erratically, which was interpreted as an agitated state. The 166 dB re 1 µPa level has been used as the threshold level for a behavioural disturbance response by NMFS and applied in the Arctic Programmatic Environment Impact Statement (PEIS) (NSF 2011). In addition the 175 dB re 1 µPa level from McCauley et al. (2000b) this level has been recommended as a criterion for behavioural disturbance. In addition, the Recovery Plan for Marine Turtles in Australia (Department of the Environment and Energy et al. 2017) acknowledges the 166 dB re1 µPa SPL reported by McCauley et al. (2000b) as the level that may result in a behavioural response to marine turtles.

The thresholds for impulsive noise suggested by Popper et al. (2014) shown in Table 5 is no longer recommended, and instead has been replaced by Finneran et al. (2017). The recommended criteria for PTS, TTS and behavioural response/disturbance are presented in Table 6.

The thresholds for vessel and non-impulsive noise suggested by Popper et al. (2014) and Finneran et al. (2017) are shown in Tables 7 and 8. The recommended criteria for PTS, TTS and behavioural response/disturbance is presented in Table 9.

Table 5. Noise exposure criteria for impulsive noise exposure for sea turtles, adapted from Popper et al. (2014).

Type of animal	Mortality and Potential mortal injury	Impairment			Behaviour
		Recoverable injury	TTS	Masking	
Turtles	> 210 dB SEL_{24h} or > 207 dB PK	(N) High (I) Low (F) Low	(N) High (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) High (I) Moderate (F) Low

Relative risk (high, moderate, low) is given for animals at three distances from the source defined in relative terms as near (N, tens of meters), intermediate (I, hundreds of meters), and far (F, thousands of meters).

Table 6. Recommended criteria for assessing acoustic effects of impulsive noise on sea turtles: Unweighted SPL, SEL_{24h}, and PK thresholds.

Effect type	Criterion	SPL (L_p; dB re 1 μPa)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 μPa²·s)	PK (L_{pk}; dB re 1 μPa)
Behavioural response	NSF (2011)	166	NA	
Behavioural disturbance	McCauley et al. (2000a)	175		
PTS onset thresholds* (received level)	Finneran et al. (2017)	NA	204	232
TTS onset thresholds* (received level)			189	226

* Dual metric acoustic thresholds for impulsive sounds: Use whichever results in the largest isopleth for calculating PTS onset. If a non-impulsive sound has the potential of exceeding the peak sound pressure level thresholds associated with impulsive sounds, these thresholds should also be considered.
L_p denotes sound pressure level period and has a reference value of 1 μPa.
L_{pk}, flat denotes peak sound pressure that is flat weighted or unweighted and has a reference value of 1 μPa.
L_E denotes cumulative sound exposure over a 24-hour period and has a reference value of 1 μPa²s.

Table 7. Acoustic effects of vessel noise exposure on sea turtles, adapted from Popper et al. (2014).

Type of animal	Mortality and Potential mortal injury	Impairment			Behaviour
		Recoverable injury	TTS	Masking	
Turtles	(N) Low (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) Moderate (I) Low (F) Low	(N) High (I) High (F) Moderate	(N) High (I) Moderate (F) Low

Relative risk (high, moderate, low) is given for animals at three distances from the source defined in relative terms as near (N, tens of meters), intermediate (I, hundreds of meters), and far (F, thousands of meters).

Table 8. Acoustic effects of non-impulsive noise exposure on sea turtles, weighted SEL_{24h}, adapted from Finneran et al. (2017).

PTS onset thresholds* (received level)	TTS onset thresholds* (received level)
220	200

Table 9. Recommended criteria for assessing acoustic effects of non-impulsive noise on sea turtles: Relative risk and SEL_{24h} thresholds.

Effect type	Criterion	Relative risk	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)
Behaviour	Popper et al. (2014)	(N) High (I) Moderate (F) Low	NA
PTS onset thresholds (received level)	Finneran et al. (2017)	NA	220
TTS onset thresholds (received level)			200

Relative risk (high, moderate, low) is given for animals at three distances from the source defined in relative terms as near (N, tens of meters), intermediate (I, hundreds of meters), and far (F, thousands of meters).
L_E denotes cumulative sound exposure over a 24-hour period and has a reference value of 1 µPa²s.

5.2.5. Marine Mammals

It has been long recognised that marine mammals can be adversely affected by underwater anthropogenic noise. For example, Payne and Webb (1971) suggested that communication distances of fin whales are reduced by shipping sounds. Subsequently, similar concerns arose regarding effects of other underwater noise sources and the possibility that impulsive sources—primarily airguns used in seismic surveys—could cause auditory injury. This led to a series of workshops held in the late 1990s, conducted to address acoustic mitigation requirements for seismic surveys and other underwater noise sources (NMFS 1998, ONR 1998, Nedwell and Turnpenny 1998, HESS 1999, Ellison and Stein 1999). In the years since these early workshops, a variety of thresholds have been proposed for both injury and disturbance. The following sections summarize the most recent development of thresholds; however, this field remains an active research topic.

5.2.5.1. Auditory Impairment

There are two categories of auditory threshold shifts (also termed Noise Induced Threshold Shift, NITS): Permanent Threshold Shift (PTS), a physical injury to an animal's hearing system; and Temporary Threshold Shift (TTS), a temporary reduction in an animal's hearing sensitivity as the result of physiological and mechanical processes in the inner ear. There are no PTS studies on marine mammals and the onset level of PTS is conventionally assumed to be at 40 dB TTS. While PTS undoubtedly constitutes an injury, TTS (as a temporary effect) was not considered in the same way. However, recent research clearly indicates that already moderate levels (<12 dB) of TTS produced an accelerated hearing loss (PTS) resulting from progressive neural degeneration with age (Kujawa and Liberman 2006, 2009, Maison et al. 2013, Kujawa and Liberman 2015). This relatively low level of TTS (12 dB) resulted in 22% neuronal loss in the inner ear; accumulated over multiple (low-level) TTS exposures this effect accumulates and leads to PTS.

The most recent criteria for assessing possible effects of impulsive sounds (such as pile driving or seismic impulses) noise and non-impulsive sound (such as vessel noise) on marine mammals are summarised in Tables 10 and 11 with frequency weighting explained in Section 5.1.4.2.

Table 10. Acoustic impairment effects of impulsive noise on marine mammals: SEL_{24h}, and PK thresholds

Hearing group	Southall et al. (2019)			
	PTS onset thresholds* (received level)		TTS onset thresholds* (received level)	
	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	PK (L_{pk}; dB re 1 µPa)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	PK (L_{pk}; dB re 1 µPa)
LF cetaceans	183	219	168	213
HF cetaceans	185	230	170	224
VHF cetaceans	155	202	140	196

* Dual metric acoustic thresholds for impulsive sounds: Use whichever results in the largest isopleth for calculating PTS onset. If a non-impulsive sound has the potential of exceeding the peak sound pressure level thresholds associated with impulsive sounds, these thresholds should also be considered.
L_{pk} denotes peak sound pressure and is flat weighted or unweighted.
L_E denotes cumulative sound exposure over a 24 h period.

Table 11. Acoustic impairment effects of non-impulsive noise on marine mammals: SEL_{24h} thresholds.

Hearing group	Southall et al. (2019)	
	PTS onset thresholds (received level)	TTS onset thresholds (received level)
	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)
LF cetaceans	199	179
HF cetaceans	198	178
VHF cetaceans	173	153

L_E denotes cumulative sound exposure over a 24 h period and has a reference value of 1 µPa²s.

5.2.5.2. Behavioural Responses

Numerous studies on marine mammal behavioural responses to sound exposure have not resulted in consensus in the scientific community regarding the appropriate metric for assessing behavioural reactions. However, it is recognised that the context in which the sound is received affects the nature and extent of responses to a stimulus (Southall et al. 2007, Ellison and Frankel 2012, Southall et al. 2016).

For non-impulsive noise, NMFS currently uses step function (all-or-none) threshold of 120 dB re 1 µPa SPL (unweighted) to assess and regulate noise-induced behavioural impacts for marine mammals (NOAA 2019). The 120 dB re 1 µPa threshold is associated with continuous sources and was derived based on studies examining behavioural responses to drilling and dredging (NOAA 2018), referring to Malme et al. (1983), Malme et al. (1984), and Malme et al. (1986), which were considered in Southall et al. (2007). Malme et al. (1986) found that playback of drillship noise did not produce clear evidence of disturbance or avoidance for levels below 110 dB re 1 µPa (SPL), possible avoidance occurred for exposure levels approaching 119 dB re 1 µPa. Malme et al. (1984) determined that measurable reactions usually consisted of rather subtle short-term changes in speed and/or heading of the whale(s) under observation. It has been shown that both received level and proximity of the sound source is a contributing factor in eliciting behavioural reactions in humpback whales (Dunlop et al. 2017b, Dunlop et al. 2018).

For impulsive noise, NMFS currently uses step function thresholds of 160 dB re 1 µPa SPL (unweighted) to assess and regulate noise-induced behavioural impacts for marine mammals (NOAA 2018, NOAA 2019). The threshold for impulsive sound is derived from the High-Energy Seismic

Survey (HESS) panel (HESS 1999) report that, in turn, is based on the responses of migrating mysticete whales to airgun sounds (Malme et al. 1984). The HESS team recognised that behavioural responses to sound may occur at lower levels, but significant responses were only likely to occur above a SPL of 140 dB re 1 µPa. Southall et al. (2007) found varying responses for most marine mammals between a SPL of 140 and 180 dB re 1 µPa, consistent with the HESS (1999) report, but lack of convergence in the data prevented them from suggesting explicit step functions.

Because of the complexity and variability of marine mammal behavioural responses to acoustic exposure, NMFS has not yet released technical guidance on behaviour thresholds for use in calculating animal exposures (NMFS 2018)[2]. An US-based expert working group lead by Brandon Southall is in the process of developing an updated approach to assess noise-induced behavioural effects on marine mammals based on the latest research results and risk assessment frameworks (see below). The only alternative criteria addressing behavioural impacts for marine mammals (Germany (BMU 2013) and The Netherlands (de Jong et al. 2015)) are tailored specifically for harbour porpoises (*Phocoena phocoena*, a HF cetacean species), both promulgating a threshold level for the onset of behavioural responses of 140 dB re 1 µPa^2·s SEL.

[2] Contrary to their first publication of marine mammals noise exposure criteria (Southall et al. 2007), in their most recent update Southall et al. (2019) do not address the topic of behavioural effects.

6. Potential Impacts from noise – General

Underwater noise can impact marine fauna in six main ways:

- Inducing stress. Stress can be acute or chronic and affect health and behaviour (Section 6.1);
- Masking or interfering with other biologically important sounds (including vocal communication, echolocation, signals and sounds produced by predators or prey) (Section 6.2);
- Disturbance leading to behavioural changes or displacement of fauna. The occurrence and intensity of disturbance is highly variable and depends on a range of factors relating to the animal and situation (Section 6.2);
- Injury to hearing or other organs. Hearing loss may be temporary threshold shift or permanent threshold shift (Section 6.4).
- Mortality and mortal injury – immediate or delayed death either due to injury or substantially reduced fitness (Section 6.5).
- Cumulative or chronic effects; repeated or long-term exposure to noise leading to additive severity of noise-induced effects (Section 6.6).

The most extensive research on the effects of noise has been conducted on humans where noise has been shown to have cardiovascular, endocrinological, neurological and auditory effects (Basner et al. 2014). Additionally, cognition is also impacted in humans (Lercher et al. 2013).

6.1. Stress

Stress is an integral, necessary part of the body's homeostasis, and certain stress levels are tolerable. At higher levels, if repeated too often, or continued over long durations stress can, however, become deleterious by creating an allostatic load to the body. This is expressed and can be measured as imbalances in the autonomic nervous system, central nervous system, neuroendocrine, and immune systems and/or result in changes in growth rate, disruption of diurnal rhythms and behavioural changes. Animals may not show overt signs of responding to an increase in noise but may nonetheless show physiological changes (e.g., Slabbekoorn et al. 2010, Kight and Swaddle 2011, Slabbekoorn et al. 2019). Symptomatic stress responses include changes in respiration rate, oxygen consumption, excretion, or food consumption rates or in chronic effects such as immune suppression. The effects of increased stress levels (acute or chronic) can be expressed through a variety of metabolic and/or physiological factors. The imbalance caused by stress in these factors can lead to immune suppression and/or result in changes in growth rate, disruption of diurnal rhythms, and behavioural changes. This cascade of effects may reduce the individual's fitness through alterations in reproduction (e.g.,Sierra-Flores et al. 2015) and, ultimately, survival (see review by Slabbekoorn et al. 2010).

Underwater sound is considered a stressor for marine animals; responses to sound exposure can range from an acute startle response to more chronic effects and can vary widely across individuals in type and magnitude according to a host of factors (see review by Busch and Hayward 2009). Direct measurements of noise-related stress responses in marine mammals from sound exposure are limited but increasing (Thomas et al. 1990, Miksis et al. 2001, Romano et al. 2004, Rolland et al. 2012). A greater amount of data are available for terrestrial mammals and other animals and, in some cases, may be useful where direct information is lacking (Wright et al. 2007). In a carefully controlled exposure experiment, Houser et al. (2020) exposed trained bottlenose dolphins to 1-s tones at different SPL. Their results show that stress-related hormones were either below detection limits (aldosterone) or levels did not show a consistent relationship with received levels (cortisol nor epinephrine). Stress responses may be species- and context-specific and depend on previous exposures (sensitisation/desensitisation, see Section 6.2, below) and the (lack of) results in the study by Houser et al. (2020) may reflect the fact that these animals have been exposed to artificial underwater sound before. However, it also gives reason to question if marine mammals interpret high-level anthropogenic sound as stressful and whether behavioural responses to sound can be equated to a physiological (endocrine) response.

6.2. Auditory Masking

Auditory masking is the process by which the threshold of hearing for one sound is raised by the presence of another (masking) sound (Erbe and Farmer 1998, Erbe 2008, Erbe et al. 2016b). This describes the reduction in audibility for one sound (termed 'signal') caused by the simultaneous presence of another sound (termed 'noise'). For this to occur, the sound must be loud enough, have similar frequency content to the signal, and must happen at the same time.

Masking is a complex phenomenon and the onset levels and severity are difficult to predict for any particular combination of sender, environment, and receiver characteristics (Erbe et al. 2016b). Masking depends on the spectral and temporal characteristics of signal and noise and is reduced if the signal and noise (masker) are separated in time, frequency, or direction (space); it can occur if the noise happens shortly before or after the signal (forward and backward masking).

The severity and extent of auditory masking depends on the spectral and temporal characteristics of both the signal and the noise. The zone of auditory masking can maximally be as large as the zone of audibility, i.e., a faint noise might mask a faint signal. However, auditory masking ends immediately after the masking sound ceases.

Masking sound can interfere with the perception of communication between conspecifics and echolocation signals and the detection of environmental, predator and prey sounds; all of these acute masking effects can have cascading consequences for communities through altered species interactions (Francis et al. 2009). Auditory masking can lead to disruption of a behaviour, lack of appropriate behavioural reactions, increased vulnerability to predators, reduced access to prey, reduced communication or listening space (Clark et al. 2009, Pine et al. 2018a, Pine et al. 2018b), changes in vocal behaviour, disruption of spawning activities, and stress (Houser et al. 2020).

The masking effect can be reduced or remedied by various active or passive mechanisms for masking-release, such as spatial or temporal release from masking (for more information, see Erbe et al. 2016b, Popov et al. 2020). The masking effect can be reduced if the signal and noise are separated in time, frequency, or direction (space).

The biological significance of acoustic masking is directly linked to the duration of the masking sound. Both anthropogenic and natural marine sound can affect hearing and partially or completely reduce an individual's ability to effectively communicate. Auditory masking is likely occurring for all marine fauna; however, masking is most frequently associated with marine mammals. Masking in fishes or other taxa has not been studied in detail.

Repeating a signal or lengthening it may reduce the amount of masking because whales seem most reactive when the sound level is increasing and at the onset of a sound. Although limited, the data suggest that stationary industrial activities producing non-impulsive sounds (such as dredging, drilling, and oil-production-related activities) result in less dramatic vocal reactions by cetaceans than do moving sound sources, particularly ships (Richardson et al. 1995). Masking and the potential effects of masking on communication and listening space of marine mammals are not fully understood and remain an area of active research (Terhune et al. 1979, Cunningham and Mountain 2014, Tennessen and Parks 2016, Cholewiak et al. 2018, Dunlop 2018, Gabriele et al. 2018, Putland et al. 2018, Dunlop 2019).

Auditory masking was investigated in a number of studies in a wide range of marine mammal species (Lemonds et al. 2011, 2012; Branstetter et al. 2013), including harbour porpoises (Kastelein & Wensveen, 2008), manatees (Gaspard et al. 2012), spotted and ringed seals (Sills et al. 2014, 2015), California sea lions (Cunningham et al. 2014), and sea otters (Ghoul and Reichmuth 2014).

Some cetaceans are known to increase the source levels of their calls, shift their peak frequencies, or otherwise modify their vocal behaviour in response to increased noise (Dahlheim 1987, Au 1993, reviewed by Richardson et al. 1995, Lesage et al. 1999, Terhune 1999, Nieukirk et al. 2005, Scheifele et al. 2005, Parks et al. 2007a, Di Iorio and Clark 2009, Hanser et al. 2009, Holt et al. 2009, Parks et al. 2009, McKenna 2011, Parks et al. 2011, Castellote et al. 2012, Melcon et al. 2012, Parks et al. 2012, Risch et al. 2012, Tyack and Janik 2013, Luís et al. 2014, Sairanen 2014, Papale et al. 2015, Dahlheim and Castellote 2016, Gospić and Picciulin 2016, Heiler et al. 2016, Martins et al. 2016, O'Brien et al. 2016, Parks et al. 2016a, Parks et al. 2016b, also Bittencourt et al. 2017).

6.3. Behavioural Responses

The intensity of behavioural responses of marine fauna to sound exposure ranges from subtle responses, which may be difficult to observe and have little implication for the affected animal, to obvious responses, such as avoidance or panic reactions. Given that the sound is audible to the individual the behavioural responses include in approximate order of increasing severity but decreasing likelihood:

- Looking or increased alertness;
- Minor behavioural responses such as modifications associated with auditory masking (see Section 6.2);
- Cessation of feeding or social interactions;
- Temporary avoidance behaviour (emerging as one of the more common responses);
- Modification of group structure or activity state;
- Habitat abandonment; and
- Injury or death via direct response or possible exacerbated by physiological factors (see Section 6.5).

The context in which the sound is received by an animal affects the nature and extent of responses to a stimulus. The threshold for elicitation of behavioural responses depends on received sound level, as well as multiple contextual factors such as the activity state of animals exposed to different sounds, the type of sound, spatial relations between a sound source and receiving animals, the gender, age, and reproductive status of the receiving animal and the and novelty of or previous exposure to the sound (Ellison et al. 2012).

Previous exposure to a sound can influence the severity of a behavioural response, leading to an increased or decreased tolerance to the sound. A novel acoustic stimulus may initially provoke a substantial anti-predator response (Voellmy et al. 2016). Behavioural "habituation is the relative persistent waning of a response as a result of repeated stimulation to that novel stimulus" (Thorpe 1963, Bejder et al. 2009). Habituation is a process involving a reduction in response over time as individuals learn that there are neither adverse nor beneficial consequences of the occurrence of the stimulus. Sensitisation refers to the opposite phenomenon, an increasing "behavioural responsiveness over time when animals learn that a repeated or ongoing stimulus has significant consequences for the animal" (Richardson et al. 1995). Individuals that are sensitised to acoustic stimuli (such as emitted by anthropogenic activities) will thus exhibit a progressive intensification of their response to these stimuli, e.g., by fleeing farther and faster when they encounter the stimulus, or by exhibiting responses at progressively lower stimulus intensities. Since habituation and sensitisation constitute learning processes that are ongoing, they reflect an individual's cumulative experience with anthropogenic activities, including the number and outcome of its exposures to anthropogenic stimuli over the course of its lifetime (Knight and Temple 1995). Tolerance describes the "intensity of disturbance that an individual […] tolerates without responding in a defined way" (Nisbet 2000 p. 315).

Acoustic risk functions (or ''dose-response'' functions) relate an exposure to the probability of response. They are a useful approach for assessing the potential for behavioural responses to occur; they assume that the probability of a response depends first on the ''dose'' (in this case, the received level of sound) and that the probability of a response increases as the ''dose'' increases (e.g., Dunlop et al. 2017b). Based on observations of various animals the relationship represented by an acoustic risk function is a more robust predictor of the probable behavioural responses of marine mammals to noise exposure (NOAA 2018). However, no such function has yet been developed for exposure to noise from acoustic sources other than military sonar. Defining such a function is difficult due to the aforementioned complexity, resulting from the array of potential environmental and other contextual effects (Ellison et al. 2012).

This complexity and variability of marine mammal behavioural responses to acoustic exposure, along with missing relevant information resulted in lack of up-to-date guidance to regulate noise-induced behavioural responses by NMFS and other national regulators. Currently, NMFS still refers to SPL of 120 dB and 160 dB re 1 µPa (NOAA 2019) for non-impulsive and impulsive sounds, respectively (Section 5.2.5). Other regulatory guidelines include species-specific and/or sound-type specific criteria (e.g., BMU 2013). These behavioural criteria, however, are conservative estimates. Moreover, they will vary between functional hearing groups and species due to differences in hearing sensitivity and, as mentioned, they will vary with the behavioural context.

When measuring behavioural responses observed from captive marine animals held in an enclosure or tank it is important to realise that they do not necessarily reflect the full range of natural responses in the wild and conclusions should not be extrapolated to other contexts (Popper et al. 2014; Hawkins et al. 2015; Lucke et al. 2016). Erbe et al. (2019) provide an excellent literature review of behavioural effects of vessel noise on marine mammals.

6.4. Noise-Induced Threshold Shift (NITS)

Exposure to sufficiently intense sound may lead to an increased hearing threshold in any living animal capable of perceiving acoustic stimuli (Finneran 2015). If this shift is reversed and the hearing threshold returns to normal, the effect is called a temporary threshold shift (TTS). The onset of TTS is often defined as threshold shift of 6 dB above the normal hearing threshold (Southall et al. 2019). If the threshold shift does not return to normal, the residual shift is called a permanent threshold shift (PTS).

Hearing loss occurs naturally in marine mammals, most likely explained by advancing age, diseases or congenital defects (Ridgway and Carder 1997, Mulsow et al. 2011). Threshold shifts can also be caused by acoustic trauma from a very intense sound of short duration, as well as from exposure to lower level sounds over longer time periods (Houser et al. 2017). Injury to the hearing apparatus of a marine animal may result from a fatiguing stimulus measured in terms of sound exposure level (SEL), which considers the sound level and duration of the exposure signal. Intense sounds may also damage the hearing apparatus independent of duration, so an additional metric of peak pressure (PK) is needed to assess acoustic exposure injury risk. Noise-induced effects mediated by particle motion have not been studied to date and it is unclear what the exposure thresholds for marine animals sensitive to particle motion are.

The severity of TTS is a function of recovery time and is expressed as the magnitude of the shift in hearing sensitivity relative to pre-exposure sensitivity and the duration of hearing impairment. TTS occurs at lower sound levels than PTS. Though the relationship between the onset levels of TTS and the onset levels of PTS is not fully understood for marine mammal species, PTS onset acoustic thresholds have been extrapolated from marine mammal TTS measurements using growth rates from terrestrial and marine mammal data (Finneran et al. 2017).

An important difference between marine fishes and marine mammals with regard to NITS is the fishes' apparent ability to regenerate their hair cells to a fully functional state within weeks after a detrimental exposure. The processes involved in the recovery are not fully understood yet and that there is conflicting evidence from sound exposure studies, such as McCauley et al. (2003). Noise-induced permanent threshold shift has not been reported for fishes yet, which may be explained by the apparent ability to recover hair cells. These findings could also suggest that the process of sensory hair cell death and regeneration is species-specific. Recovery from TTS takes a few days to a few weeks in fishes (Scholik and Yan 2001, Mackenzie and Raible 2012), and the time course for recovering from hearing loss likely depends on the species, its normal hearing sensitivity, the sound exposure intensity and duration, and the amount of sensory epithelial damage (Smith and Monroe 2016). Noise-induced PTS has not been reported for fishes yet, which may be explained by their apparent ability to recover hair cells.

As in other animal groups, NITS in fishes can result from mutations, treatment with ototoxic chemicals, and exposure to excessive levels of underwater noise. NITS has been demonstrated in a number of fish species (Popper and Clarke 1976, Scholik and Yan 2001, Amoser et al. 2004a, Smith et al. 2004, Popper et al. 2005a, Popper et al. 2007) after exposure to different types of sounds. Multiple exposures to very intense sounds (SPL well over 190 dB re 1 μPa) or long-term exposure to lower-level sounds were necessary to cause NITS. The onset thresholds for NITS, however, varied between individuals and species (Popper et al. 2005b, Popper et al. 2007, Hastings et al. 2008, Hastings and Miksis-Olds 2012). Not all experiments involving exposure to intense sound, however, caused NITS in the exposed fishes; some species exhibited no or minimal hearing threshold shifts following intense sound exposure (Smith and Monroe 2016).

The biological significance of NITS in fishes is mediated by the fact that perception of underwater sound for communication purposes is linked to the regulation of social and reproductive behaviours of fishes; fishes listen to other fishes (both conspecific and heterospecific) and other aquatic sound-producing organisms (Lagardère et al. 2005, Vasconcelos et al. 2011, McIver et al. 2014) such as their predators. With sound playing such a vital role in a variety of behaviours, fishes of all life stages face a higher risk of mortality and decreased fitness if their hearing is impaired.

In early life stages of reef fishes, impaired auditory or vibratory sensitivity has the potential to impair their orientation during homing phase (Montgomery et al. 2006, Munday et al. 2009, Vermeij et al. 2010, Radford et al. 2011, Simpson et al. 2011, Rossi et al. 2015). With sound as navigational cue for finding their new habitats, NITS has the potential of impacting these individuals in a sensitive life stage thus reducing their chance of survival.

6.5. Mortality

Exposure to excessive levels of impulsive sound or events characterised by rapid overpressure in water can kill and injure marine fauna (Carlson et al. 2011). Impulsive sounds, with rapid changes in pressure, are more damaging to tissues than gradual changes (Popper et al. 2014).

Mortality is either a direct effect of the exposure (in case of severe injury) or indirect if an animal is moderately injured. Data on sound-induced mortality has been documented for fish (Caltrans 2001), but is scarce for marine mammals (Ketten 1995, Landsberg 2000) and only hypothesised for other taxa (Guerra et al. 2004).

Exposure to intense underwater sound may not directly result in death or injury; however, it may be one of the indirect causative factors in death or injury to marine mammals. Marine mammal strandings of beaked whales (D'Amico et al. 2009) and common dolphin (Jepson et al. 2013), are thought to be a result of the animals' behavioural responses to acoustic exposure to military mid-frequency sonar. According to the US Navy's Atlantic Fleet Training and Testing Final Environmental impact Statement "Sonar use during exercises …… has been identified as a contributing factor in five species mass stranding events: Greece in 1996, the Bahamas in March 2000, Madeira Island, Portugal in 2000, the Canary Islands in 2002 and Spain in 2006. These five mass strandings resulted in approximately 40 known, scientifically verifiable sonar-related deaths among cetaceans consisting mostly of beaked whales." (US Dept. of the Navy, 2013).

Investigating the mass stranding of approximately 100 melon-headed whales in the Loza Lagoon system in Madagascar lead to the conclusion that the use of a 12 kHz multibeam echosounder (with SPL of 236 to 246 dB re 1 µPa and per pulse SEL of 218 to 224 dB re 1 $\mu Pa^2 \cdot s$) are "the most plausible and likely initial behavioral trigger of the stranding event, but that a variety of secondary factors contributed to or ultimately caused mortalities […]" (Southall et al. 2013).

6.6. Cumulative and Chronic Effects

Noise-induced effects can be acute (such as acoustic masking), or chronic (including altered distribution), lasting from the immediate duration of sound exposure to several days or weeks if animals are displaced from their preferred areas during an activity (Engås et al. 1996, Slotte et al. 2004, Løkkeborg et al. 2012b, 2012a, Streever et al. 2016) and can be permanent in case of PTS, for example.

Historically, most acoustic effects studies on marine animals have focused on short-term and acute effects from single, individual high-intensity sounds (e.g., the near-field sounds from seismic airguns, sonar, and impact pile driving). Recently there has been more interest in the effects of sound exposures received by marine mammals over larger spatial and temporal extents (Clark et al. 2009, Hatch et al. 2012). These long-term exposures, and the resulting chronic effects, may in some cases be more relevant to marine animals than short-term acute effects, especially for communications between conspecifics (see review by the National Academies of Sciences 2016).

Effects of a single exposure to a single stressor (such as noise) can be exacerbated by repeated exposures (cumulative – spatially and temporally) or through simultaneous exposure to multiple stressors (additive – e.g., noise and chemical pollution). The following scenarios can be considered:

- Acute effects following:

    - Single exposure to a single stressor
- Chronic effects following:
    - Continuous exposure to the same type of stressor
    - Continuous exposure to different types of stressors
- Cumulative effects following:
    - Repeated exposure to the same type of stressor
    - Repeated exposure to different types of stressors
- Additive/ aggregate effects following:
    - Simultaneous exposure to multiple variations of the same stressor
    - Simultaneous exposure to multiple variations of different stressors

Acute exposure and cumulative exposure to sound over time has been investigated in marine mammals and is reflected in the most recent set of noise exposure criteria (NMFS 2018; Southall et al. 2019) under the SEL criterion.

The simultaneous exposure to sounds from multiple sources is likely to induce stronger effects in marine animals that are currently not accurately represented by assessments of the most prevalent source alone (Wright and Robertson 2015). There may be, for example, an increased risk for TTS as well as for masking, stress and related effects. Differences in the frequency spectrum, temporal pattern and other acoustic parameters of the overlapping sounds and the complexity of the physiological and behavioural effects make it complicated, if not impossible to assess the cumulative and additive effects. Accordingly, the existing noise exposure criteria do not account for such combined exposure to different types of noise.

A cumulative effect may also exist with regard to the background noise level to which an animal is subjected to during exposures to intense sounds. Hamernik et al. (1974) exposed chinchillas to moderate levels of non-impulsive noise prior to exposure to intense impulsive noise. Their audiometric and histological findings show that the combination of two noise exposures, shown to be safe individually, cause NITS exceeding the additive effects of either component.

Marine species experience acoustic stimuli not in isolation from other environmental stressors such as chemical ocean pollution, habitat modification, food depletion and many other anthropogenic drivers with potentially detrimental effects (Kappel 2005, Halpern et al. 2008). These stressors can directly interact with each other in complex ways – they can be potentiating (i.e., being additive or multiplicative), counteracting (i.e., being subtractive or divisive) or non-interactive, and it should be noted that temporal separation is sufficient to remove any interaction effect.

Many of the drivers affecting marine animals are themselves affected by larger-scale ecological drivers. For example, global climate change is an ecological driver that changes the marine environment and exposes marine life to the stressors of warming and ocean acidification. Similarly, predators, prey, and competitors of marine mammals are potential stressors whose distributions are affected by ecological interactions of these stressors (National Academies of Sciences 2016).

With regard to marine animals, cumulative and additive effects from multiple sound sources as well as other stressors have been identified as important parameters for the assessment of human impacts (National Research Council, NRC 2005; Williams et al. 2015; Ellison et al. 2016).

The problem of assessing cumulative effects is exacerbated by limited data on relationships between stressors and vital functions in marine mammals, mainly owing to their cryptic lifestyle. This data deficiency makes it almost impossible to dissociate the assessment of effects caused by noise exposure from that of other stressors. There are no standards for assessment of cumulative exposure to underwater sound.

7. Species/Taxon-Specific Impacts

This section provides detailed information on documented effects of noise exposure on marine animals. Species are grouped at a high taxonomic level in each subsection, and information is differentiated by type of sound source and impact category if available.

7.1. Marine Invertebrates

Exposure to anthropogenic sound sources could have a direct consequence on the functionality and sensitivity of the sensory systems of marine invertebrates and affect their physiology, behaviour, and cause noise-induced trauma. For most species, however, the sensory sensitivity to underwater sound and susceptibility to noise-induced effects has not been investigated. Available scientific information is scarce and often derived from laboratory studies, in most cases with insufficient control over the particle motion field in the test environment. Lack of quantifying the most relevant input parameter for the sensory system of marine invertebrates, however, reduces the robustness of any conclusions drawn from such studies.

7.1.1. Plankton

7.1.1.1. Impulsive Sound Sources

7.1.1.1.1. Seismic Airguns

Parry et al. (2003) studied the abundance of plankton after exposure to airgun sounds but found no evidence of mortality or changes in catch-rate on a population level.

Contrary to other studies, McCauley et al. (2017) found that after exposure to airgun sounds generated with a single airgun (150 in^3) zooplankton abundance decreased and mortality in adult and larval zooplankton increased two- to threefold when compared with controls. In this first large-scale field experiment on the impact of seismic activity on zooplankton, they used a sonar and net tows to measure the effects on plankton. They determined a maximum effect-range of horizontal 1.2 km. Their findings contradicted the conventional idea of limited and very localised impact of intense sound in general, and seismic airgun signals, on zooplankton. Their results indicated that there may be noise-induced effects on these taxa and that these effects may even be negatively affecting ocean ecosystem function and productivity. The study was compromised by methodological design of the study (small sample sizes, large daily variability in the baseline and experimental data) and the statistical robustness of the data and conclusions (large number of speculative conclusions that appear inconsistent with the data collected over 2 days) (Richardson et al. 2017).

The Commonwealth Scientific and Industrial Research Organisation (CSIRO, Richardson et al. 2017) simulated the large-scale impact of a seismic survey on zooplankton using the mortality rate inferred by McCauley et al. (2017). The CSIRO study aimed to estimate the spatial and temporal impact of seismic activity on zooplankton on the Northwest Shelf of Western Australian based on McCauley et al findings. The major findings of the CSIRO study were that seismic activity substantially impacted zooplankton populations on a local scale within or near the survey area; however, on a regional scale the impacts were minimal and were not discernible over the entire Northwest Shelf Bioregion. The study found that the time for the zooplankton biomass to recover to pre-seismic levels inside the survey area, and within 15 km of the area, was only three days following the completion of the survey. This relative quick recovery was due to the fast growth rates of zooplankton, and the dispersal and mixing of zooplankton from inside and outside the impacted region (Richardson et al. 2017). Richardson et al. (2017) showed that zooplankton communities can begin to recover during the seismic survey in good oceanic circulation or they can “bottom out” at a maximum impact level (presumably where growth rates and/or zooplankton entering the survey area roughly approximate mortality rates) after 23–30 days of commencing survey operations.

Fields et al. (2019) exposed zooplankton (copepods) to seismic pulses at various distances up to 25 m from a seismic source. The source levels produced were estimated to be 221 dB re 1 μPa^{2}s, comparable to the far-field source levels associated with some commercial-scale seismic surveys. The study observed an increase in immediate mortality rates of up to 30% of copepods in samples at distances of 5 m or less from the airguns compared to controls. Mortality one week after exposure was significantly higher by 9% relative to controls in the copepods placed 10 m from the airguns. Fields et al. (2019) also reported that no sublethal effects occurred at any distance greater than 5 m from the seismic source. The findings of the study indicate that the potential effects of seismic pulses to zooplankton are limited to within ~10 m from the seismic source. Fields et al. (2019) also note that the findings of the McCauley et al. (2017) study are difficult to reconcile with the body of other available research and may, therefore, provide an overly conservative estimate of the potential effects of seismic pulses to zooplankton.

Hawkins et al. (2014) generated synthetic impulse sounds (resembling pile driving or airgun impulses) in a behavioural response study in open water and documented the effects on fishes and zooplankton (such as copepods and larvae) using an echosounder. The typical reaction documented for zooplankton was a sudden “dent” in the top of the layer at the onset of the sound sequence, indicating that the animals either dispersed or changed depth, away from the source. The change did not persist for the whole duration of the exposure. The authors found that zooplankton aggregations within the ensonified area responded to received sound pressure levels ranging from 156 dB to 159 dB re 1 µPa peak-to-peak (PK-PK) while larger individuals (probably ctenophores and other coelenterates) did not respond to the sound exposure.

7.1.1.1.2. Offshore Pile Driving

The effects of impulsive sound on fish eggs and larvae were investigated in the context of offshore pile driving. Bolle et al. (2012) investigated the risk of mortality in common sole larvae by exposing them to impulsive stimuli in an acoustically well-controlled study. Even at the highest exposure level tested, at an SEL of 206 dB re 1 $\mu Pa^2 \cdot s$ (corresponding to 100 strikes at a distance of 100 m) no statistically significant differences in mortality was found between exposure and control groups.

7.1.1.2. Non-Impulsive Sound Sources

7.1.1.2.1. Offshore Drilling

Information specific for effects of sound emitted by offshore drilling activities on plankton is not available.

7.1.1.2.2. Vessels

Information specific for effects of sound emitted by vessel operations on plankton is not available.

7.1.2. Bivalves and decapods

7.1.2.1. Impulsive Sound Sources

7.1.2.1.1. Seismic Airguns

Aguilar de Soto et al. (2013) indicated that New Zealand scallop (*Pecten novaezelandiae*) larvae exposed to extended periods of airgun signals during their ontogeny may be negatively affected. The authors found an increase in abnormality and mortality rates in scallop larvae after continued exposure to playbacks of intense airgun signals in a laboratory experiment. These results indicated that there may be species-specific differences in sensitivity of early life stages to sound exposure.

In a field study, Przeslawski et al. (2016) focused on potential short-term impacts of marine seismic surveys on scallops in the Gippsland Basin. Commercial scallops (*Pecten fumatus*) were not abundant in the study area, and there was no evidence of mortality or change in the condition of scallops two months after a marine seismic survey ended. Analysis of images and samples revealed site-specific variance in scallop abundance, size, condition, and assemblages were higher than the observed effects from exposure. The analysis of the acoustic parameters, however, is likely compromised by the erroneous use of acoustic modelling methods and no close range recordings.

Day et al. (2016a) conducted an open water study on the effects of exposures of rock lobster (*Jasus edwardsii*) and scallop to impulsive noise produced by an airgun. Their study used field and laboratory experimental approaches to investigate potential impacts of marine seismic surveys on these species. Their field study used a real airgun and had better control over the relevant experimental parameters than other reported studies. Accordingly, their results are more relevant than those obtained under laboratory conditions with animals exposed to simulated signals.

It is likely that particle motion and interface waves are the more relevant stimulus. Day et al. (2016a) provide a regression of particle acceleration versus range for the single 150 in^3 seismic airgun used in the study and showed that acceleration at the 10 and 100 m ranges were typically 26 and 5 ms^{-2}, respectively. The study also references an unpublished maximum particle acceleration measurement of 6.2 ms^{-2} from a 3130 in^3 seismic airgun array at 477 m range in 36 m of water.

Morris et al. (2018) assessed the effects of industry scale seismic exposure on catch rates of snow crab (*Chionoecetes opilio*) along the continental slope of the Grand Banks of Newfoundland. In a Before-After-Control-Impact study over two years they did not find evidence supporting the contention that seismic activity negatively affects catch rates in shorter term (i.e. within days) or longer time frames (weeks). However, significant differences in catches were observed across study areas and years. Their results suggest that if effects from exposure to seismic airgun impulses on snow crab harvests do exist, they are smaller than changes related to natural spatial and temporal variation.

Day et al. (2019) tested the impact of seismic surveys on the righting reflex and statocyst morphology of the rock lobster. Their results show that exposure to seismic airgun impulses with calculated received PK levels of up to 205 dB re 1 µPa and maximum SEL of 191 dB re 1 $\mu Pa^2 \cdot s$ can cause morphological damage to the sensory organ of rock lobster. Two reflex behaviours, tail tonicity or extension and righting behaviour, were assessed. These reflexes have been used in lobster fishery industries in grading animals for their likelihood of survival. While results for tail tonicity were inconclusive, there was a significant response to exposure in the righting response, which is a more complex reflex requiring neurological control and muscle coordination. The lobsters showed impaired righting and significant damage to the sensory hairs of the statocyst. Reflex impairment and statocyst damage persisted over the course of the experiments and did not improve following moulting.

Consistent with other studies of high-intensity, low-frequency sound exposure of crustaceans and molluscs (reviewed by Edmonds et al. 2016, Carroll et al. 2017), the study found no evidence of mass mortality directly following airgun exposure. Consequently, the authors rejected the hypothesis that exposure to seismic airguns causes immediate mass mortality.

Day et al. (2017) investigated the effect of exposure to airgun impulses on scallops (*Pecten fumatus*). The authors conclude that exposure to seismic signals significantly increases mortality, particularly over a chronic (months post-exposure) time scale, though not beyond naturally occurring rates of mortality. The calculated maximum PK levels at the position of the bivalves reached 213 dB re 1 µPa and maximum SEL of 198 dB re 1 $\mu Pa^2 \cdot s$.

Studies on the impacts of underwater explosions on several species of bivalve, including two pearl oyster species, indicated strong resilience to the shock waves created by the detonation of explosives underwater. Chalmer (1986) found that no mortality occurred in the exposed animals over a 13-week period and at a minimum exposure range of 1 m from the blast centre. These studies do not offer any insights as to the distances at which sub-lethal effects (such as morphological, biochemical and physiological changes being indicators of some level of stress in an animal) could occur.

7.1.2.1.2. Offshore Pile Driving

Information specific for effects of sound emitted by offshore pile driving activities on bivalves and decapods is not available.

7.1.2.2. Non-Impulsive Sound Sources

7.1.2.2.1. Offshore Drilling

Information specific for effects of sound emitted by offshore drilling activities on bivalves and decapods is not available.

7.1.2.2.2. Vessels

Shore crabs (*Carcinus maenas*) experiencing repeated ship noise playback showed initial stress responses (Wale et al. 2013). On first exposure, the animals consumed more oxygen, indicating a higher metabolic rate. Filicotto et al. (2016) examined the effects of recorded boat noise on the behaviour and biochemistry of the common prawn (*Palaemon serratus*). The exposure elicited changes in locomotor patterns and caused physiological and behavioural effects that the authors identified as stress-related responses.

7.1.2.2.3. Other Non-Impulsive Sound Sources

Two tank-based experiments investigated the physiological and behavioural effects of sound exposure on marine invertebrates. The sound generated by tidal and wind turbines was found to delay the time to metamorphosis between larval stages in estuarine crabs (Pine et al. 2012). Celi et al. (2013) documented statistically significant variations in haemato-immunological parameters as well as a reduction in agonistic behaviour in red swamp crayfish (*Procambarus clarkii*) after constant exposure to frequency sweeps over a duration of 30 min. The signals covered a frequency range between 0.1–25 kHz and reached a peak amplitude 148 dB re 1 µPa at 12 kHz.

7.1.3. Cephalopods

7.1.3.1. Impulsive Sound Sources

7.1.3.1.1. Seismic Airguns

Guerra et al. (2004) found statocyst and organ damage in seven stranded giant squids and considered these findings as circumstantial evidence for noise-induced effects caused by nearby seismic surveys. McCauley et al. (2000a) and Fewtrell and McCauley (2012) conducted controlled exposure experiments with caged squid (*Sepioteuthis australis*) using a single seismic airgun as the sound source. They found that in one trial, where the received level of the first seismic air gun impulse was 162 dB re 1 $\mu Pa^2 \cdot s$, the squid inked (an alarm response). This response was not observed again within this trial, however the authors stated that it was unknown if this was due to depleted ink reserves or habituation. In two other trials, the initial received levels were lower (132 and 146 dB re 1 $\mu Pa^2 \cdot s$ per-pulse SEL), and although the received levels did exceed 162 dB re 1 $\mu Pa^2 s$, no inking behaviour was observed. Exposure to airgun impulses at sound levels greater than 147 dB re 1 $\mu Pa^2 \cdot s$ induced the caged squid to start jetting away from the sound source (i.e., an avoidance behaviour). The authors hypothesised that the results also suggest that a gradual increase in received levels and prior exposure to seismic air gun impulses decreases the severity of the alarm responses in this species, i.e. the animals likely habituated to the sound exposure. This aligns with findings of general habituation in response to predators in squid (Long et al. 1989). While Fewtrell and McCauley (2012) stated that their results were preliminary, the level associated with inking (162 dB re 1 $\mu Pa^2 \cdot s$ per-pulse SEL) has been considered as a startle response threshold[3] for both squid and octopus.

[3] It is worth noting that perception of sound impulses in squid are most likely mediated by particle motion and that the relevant levels were not reported by the authors.

7.1.3.1.2. Offshore Pile Driving

No scientific information is available on the potential of noise-induced effects on cephalopods following exposure to impact pile driving impulses.

7.1.3.2. Non-Impulsive Sound Sources

7.1.3.2.1. Offshore Drilling

Information specific for effects of sound emitted by offshore drilling activities on cephalopods is not available.

7.1.3.2.2. Vessels

Information specific for effects of sound emitted by vessel operations on cephalopods is not available.

7.1.3.2.3. Other Non-Impulsive Sound Sources

Mooney et al. (2016) tested unconditioned behavioural responses to tonal signals in squid (*Doryteuthis pealeii*). The reactions elicited by sound exposure from 80 Hz to 1 kHz ranged from inking and jetting to body pattern changes and fin movements. Animals responded to the lowest sound levels in the 200–400 Hz range.

André et al. (2011) and Solé et al. (2013) provide evidence of acoustic trauma in different cephalopod species (*Sepia officinalis*, *Octopus vulgaris*, *Loligo vulgaris*, and *Illex condietii*) that they exposed (underwater) for 2 h to low-frequency sweeps between 50–400 Hz (1 s duration) generated by an in-air speaker. The received level at the animals' position was 157 dB re 1 µPa with peak levels (unspecified) up to 175 dB re 1 µPa. Both studies report permanent and substantial morphological and structural alterations of the sensory hair cells of the statocysts following noise exposure with no indication of recovery. In a more recent experiment, Solé et al. (2017) exposed common cuttlefish (*Sepia officinalis*) to tonal sweeps between 100–400 Hz in a controlled exposure experiments in open water. Their results show a clear statistical relationship between the cellular damage detected in the sensory cells of the individuals exposed to the sound sweeps and the distance to the sound source. The authors measured the particle motion and pressure of the signals received by the animals. Due to the signal type (frequency sweep), they could only provide the maximum received levels or an estimate thereof, respectively; the maximal particle motion level was 0.7 ms^{-2} observed at 1 m depth, the pressure reached levels of 139–142 dB re $1µPa^2$. The sound pressure levels reported are only slightly higher than the hearing threshold determined for longfin squid (*Loligo pealeii*), another decapodiforme cephalopod, measured by Mooney et al. (2010). The maximum particle motion (reported in terms of particle acceleration) reported by Solé et al. (2017) is in the same order of magnitude as the behavioural thresholds measured at 100 Hz by (Packard et al. 1990) using a standing wave acoustic tube.

7.1.4. Other Benthic Invertebrate Species

Many marine invertebrates are permanently, or at least sporadically, in contact with bottom sediment. The sediment, however, does not follow exactly, or at all, the movement of the surrounding water. Therefore, exposure to underwater sound will result in a relative movement between the body of these animals and the oscillating water column. Accordingly, marine benthic invertebrates face a different situation and perception from free-swimming or neutrally buoyant animals such as demersal or pelagic fish or marine mammals. In a discussion of the pressure-related as well as the particle motion-related sensitivity in marine invertebrates, it is therefore important to also consider the propagation of vibration through the ground. For benthic organisms, it is likely that this type of vibration is of similar if not greater importance than the water-borne vibration or even the compressional component of a sound (Roberts and Elliott 2017). The published scientific information on vibration sensitivity in marine invertebrates is extremely scarce (Roberts et al. 2015, Roberts et al. 2016). Most information on vibration sensitivity has been derived from semi-terrestrial species known to use vibration in mating behaviour (Aicher and Tautz 1990). Only a small number of studies have indicated reception of vibration and behavioural responses in bivalves, which include closing syphons and, in more active molluscs, moving away from the substrate (Mosher 1972, Ellers 1995, Kastelein 2008). Nevertheless, to date, there is no convincing evidence for any significant effects induced by non-impulsive noise in benthic invertebrates.

Moreover, given the rapid attenuation of vibrational signals beyond the near field of a sound source (Morley et al. 2014), it is unlikely that these stimuli are causing more than behavioural effects (such as flight or retraction) or physiological (e.g., stress) responses.

In a field experiment, Nedelec et al. (2014) investigated the effect of long-term exposure to non-impulsive noise on the development and survival of the early life stages of the sea hare (*Stylocheilus striatus*). They found that in comparison to a control experiment with ambient-noise playback, the exposure to 12-h playbacks of small boat noise stopped development of nudibranch embryos by 21% and increased the mortality of the remaining nudibranch larvae by 22%.

Heyward et al. (2018) monitored different types of corals *in situ* before, during and after a four-day 3-D seismic survey. They found no detectable effect on soft tissues or skeletal integrity of the corals after exposure to seismic airgun signals at levels of up to 204 dB re 1 $\mu Pa^2 \cdot s$ SEL and 226 dB re 1 µPa PK. There is no further information available on noise-induced effects on benthic organisms (other than bivalves and decapods, see Section 7.1.2) specific to a particular type of sound source.

7.2. Fish

Studies on noise-induced effects on fish are mainly focused on behavioural and auditory effects.

The onset level of behavioural responses in fishes varies greatly between and within species, including between fishes of different ages and sizes, the behavioural and social context, and the motivation of the fishes. Existing data on behavioural responses do not provide a clear dose-response relationship. Consequently, it is currently impossible to determine single value thresholds for the onset of behavioural reactions. Instead, broad response and effect categories such as those proposed by Popper et al. (2014) (see Section 5.2.3) seem most reasonable and may guide regulatory decisions in this context.

Contrary to marine mammals, TTS and PTS have less ecological relevance for fishes as they can regenerate their hearing sensitivity sensory cells, therefore, affecting their fitness (i.e., including ability to communicate and mate) only temporarily. Moreover, the detection of acoustic signals is mostly mediated in fishes through particle motion rather than sound pressure, which reduces the ecological relevance of auditory impairment in fishes even further.

The fact that some fish species, however, have also the ability to detect sound pressure indicates that this sensory system has a functional role for these species and cannot be completely ignored. More information about the role of the hearing system and the particle motion sensitivity of fishes is required to allow for a more comprehensive assessment of noise-induced effects. In the absence of such information, behavioural responses and non-auditory injury are better descriptors for noise-induced effects. The susceptibility for all types of effects seems directly related to the existence, form, and function of a swim bladder, which lead to division of fish species in three categories (see Section 5.2.3 and Popper et al. (2014)).

Extreme levels of particle motion may also have the potential to injure tissues although this has not been demonstrated for any source yet (Popper et al. 2014).

7.2.1.1. Impulsive Sound Sources

7.2.1.1.1. Seismic Airguns

<u>Stress</u>

Stress effects caused by exposure to seismic signals was investigated in an *in situ* experiment on caged sea bass (*Dicentrarchus labrax*) by Santulli et al. (1999). The animals showed increased levels of various biochemical parameters as primary and secondary stress markers in their tissues after exposure to airgun emissions, while no physical trauma or mortality was observed. The physiological responses disappeared within 72 h, indicating a recovery of homeostasis following the exposure. McCauley et al. (2003) conducted a similar study in caged pink snapper (*Pagrus auratus*) but did not find any significant biochemical indicators of stress in the exposed animals.

Behavioural Responses

Pearson et al. (1992) showed that exposure to airgun sound can cause changes in schooling patterns and distribution of captive rockfish (*Sebastes* spp.). Strong 'startle' responses have been observed in some fish species at received sound levels of 200–205 dB re 1 µPa, indicating that sounds at or above this level may cause more severe behavioural reaction such as avoidance. Sound levels of this intensity are likely to occur 100 to 300 m from a seismic array (McCauley 1994). Based on this, an approximate range of 200 m was estimated as the minimum distance at which fish may start avoiding an approaching seismic source.

Santulli et al. (1999) exposed caged European sea bass (*Dicentrarchus labrax*, a demersal species) to a 2,500 in^3 seismic source. Limited response was observed at 2.5 km distance. A startle response was observed when the array was at a distance of approximately 800 m, but after passing within 180 m, fish behaviour appeared to return to normal within 1 hour. Exposures of fish in the wild would likely result in avoidance of high sound levels prior to the seismic source approaching to as close a range and to as high sound levels as the captive fish in the experiment were exposed to. Wardle et al. (2001) studied the behavioural reaction of reef-associated fishes in their natural environment in response to emissions from a single seismic airgun using underwater video and an acoustic tracking system. They observed startle responses and some changes in the movement patterns of fish. Similar to this, Hassel et al. (2004) observed startle responses in fish species exposed to airgun sounds.

Most work on the effect of airgun signals on free-swimming fishes has been conducted on demersal species. Peña et al. (2013) used an omnidirectional fisheries sonar to study the response of free-ranging herring schools to the approach of a full-scale seismic airgun survey. Throughout the study period, the herring swam slowly against the predominant northeast current, with a net displacement along with the current. The mean swimming speed after subtracting the drift velocities was 0.35 m/s, and the mean response speed in the direction away from the airgun array was 0.22 m/s. No changes were observed in swimming speed, swimming direction, or school size that could be attributed to the transmitting seismic vessel as it approached from a distance of 27 to 2 km, over a 6-hour period. The unexpected lack of a response to the seismic survey was interpreted as a combination of a strong motivation for feeding, a lack of suddenness of the airgun stimulus, and an increased level of habituation to the repeated presentation of the same seismic signal.

Several studies in Norwegian waters found that the horizontal and vertical distributions of both pelagic and demersal fishes were altered during and after airgun operations (Skalski et al. 1992, Engås et al. 1996, Engås and Løkkeborg 2002, Slotte et al. 2004). The researchers were unable to observe the behaviour of fishes in response to the sound exposure. Instead, they measured catch rate of fishes as an indicator of fish behaviour. These studies reported pronounced reductions (up to 70% in longline fishing) in commercial catches from trawls and longlines and the wide-ranging displacement (up to 50 km, Slotte et al. 2004) of fish from fishing grounds.

Contradicting findings were made by Løkkeborg et al. (2012b, 2012a). They found changes in catch rates of all species studied, indicating that these species all responded to airgun sounds. However, they also showed that gillnet catches were doubled for some fish species during seismic shooting and only longline catch rates fell slightly. They explain these contradictory results by greater swimming activity versus lowered food search behaviour in fishes exposed to airgun sound emissions. Except for one species, they did not find any changes in abundance or displacement from fishing grounds. This may be correlated to less intense sound exposure compared with previous studies and strong habitat preference in some species. These findings are in general corroborated by the finding of Hawkins et al. (2014). The synthetic signals they used in their playback experiment contained generic impulsive signal characteristics that make the results applicable also to the behavioural effects of airgun sounds. The sprat and mackerel they investigated generally reacted to the impulsive sound exposure by dispersing and changing depths, which would make it difficult to detect the true scope of effects in a study relying on fisheries technology.

Free-swimming fishes were exposed to noise from seismic airguns in Mackenzie River (Northwest Territories, Canada), but no apparent change in their swimming direction or speed was observed as revealed by using a sonar (Cott et al. 2012). The received sound exposure levels reached 175 dB re 1 $\mu Pa^2 \cdot s$ and zero-to-peak sound pressure levels (PK) of over 200 dB re 1 µPa.

Behavioural observations of free-swimming fish conducted during a 3-D seismic survey at Scott Reef (Miller and Cripps 2013) show that seismic airgun emissions did not cause lethal or sub-lethal effects on fish near the operating array. At close range, the vessel approach caused fishes to cease their behaviours and move towards the seabed, but the effect was short-lived. Fishes began to feed and behave normally again within 20 minutes after the seismic survey vessel passed. Caged fishes displayed startle responses too infrequently to analyse. However, agitation levels increased with increasing received sound exposure level for the three holocentrid species (squirrelfishes and soldierfishes, Holocentroidei) but were not detectable for the blue-stripe sea perch (*Lutjanus kasmira*). Sonar observations of free-swimming fishes indicated that individual animals tended to move towards the seabed on approach of the operating airgun array, consistently out to 400 m either side of the survey test line. Schools of fishes moved towards the seabed within 200 m of the survey test line in response to the passage of the operating seismic source and stayed significantly closer to the seabed up to 63 minutes post-exposure. The vocal behaviour of fishes was unaffected during the seismic activity. Fish choruses remained unchanged with regards to timing and chorus level (at daily, lunar, and seasonal scales). These findings suggest that in the long term, the survey had little effect on the fish that produced the choruses. Visual census revealed that diversity and abundance of Pomacentridae (damselfishes and clownfishes) and non-Pomacentridae fish species (inhabiting shallow-slope regions) showed no significant changes after the seismic survey compared to the long-term temporal trend before the survey. Analysis of recordings from baited remote underwater video stations showed no detectable effects of the seismic survey on the diversity and abundance of deeper water fish communities at the spatial and temporal scales examined. Also, there were no signs of loss of individuals or of systematic re-distribution of individuals and species at any of the time scales examined.

The findings from the research at Scott Reef support those by Wardle et al. (2001), who exposed free ranging marine fish inhabiting an inshore reef to sounds from a seismic source (maximum received levels (RL) of 195–218 dB re 1 µPa PK). The study found that fishes exhibited a startle response to all received levels, but no avoidance behaviour were observed. They showed no signs of moving away from the reef, and exposure to the seismic noise did not interrupt a diurnal rhythm of fish gathering at dusk. Slight changes were recorded to the long-term day-to-night movements of two tagged pollack (*Pollachius sp.*), particularly when positioned within 10 m of their normal living positions. However, the seismic sound had little effect on the day-to-day behaviour of the resident fishes and invertebrates. Fewtrell and McCauley (2012) showed that fishes tended to remain lower in the water column and/or swim faster and form tighter schools during periods of close air-gun emissions.

Fish populations can be further impacted if behavioural responses result in deflection from migration paths, feeding grounds, or disturbance of spawning, thereby affecting recruitment of fish stocks. Available evidence suggested that behavioural changes for some fish species are insignificant and short-lived. The duration of effect is less than or equal to the duration of exposure and is expected to vary between species and individuals and be dependent on the properties of received sound (DFO 2004). Such a temporary short-range displacement of pelagic or migratory fish populations would have insignificant repercussions at a population level (McCauley 1994). For site-attached reef fish, spatial patterns of species richness, abundance, and diversity did not change after airgun noise emissions (Miller and Cripps 2013). The ecological significance of such effects is expected to be low, except where they may influence reproductive activity. However, researchers have observed that once acoustic disturbances are removed, fish return to normal behaviour within about 1 hour (Pearson et al. 1992, McCauley et al. 2000b, Wardle et al. 2001). In conclusion, it is evident that behavioural reactions can occur to impulsive signals such as seismic airgun impulses, but at this point there are no data that can be applied to develop guidelines regulating noise-induced behavioural effects on fishes.

TTS

McCauley et al. (2003) demonstrated that exposure to repeated emissions of a single airgun with a source level of 222.6 dB re 1µPa PK-PK from 5 to 15 m at the closest approach caused extensive damage to the sensory hair cells in the inner ear of caged pink snapper (*Pagrus auratus*). Although no mortality was observed, they found that an increased amount of epithelial damage occurred 58 days compared to 18 days post-exposure (i.e., no evidence of sensory cell regeneration). No hearing tests were performed to quantify hearing loss. The authors of the study acknowledged that the impact of exposure on ultimate survival of the fish was unclear.

Popper et al. (2005b) exposed three species of freshwater fish in a river to airgun signals at received SPL of up to 209 dB re 1 μPa (PK) and a mean SEL of up to 180 dB re 1 $\mu Pa^2 \cdot s$ and subsequently tested the animals for auditory threshold shifts. The amount of NITS induced by the noise exposure differed among the three species. Northern pike (*Esox lucius*) showed the largest shifts, broad whitefish (*Coregonus nasus*) intermediate levels of threshold shift, and lake chub (*Couesius plumbeus*) being least affected. Hearing loss increased with the number of seismic signals that the fish were exposed to, but in all cases hearing thresholds recovered within 18 hours. These same individuals were subsequently examined for sensory hair cell loss, but none was detected (Song et al. 2008). This suggests that any damage to the fishes may have occurred at an individual hair cell level but could not be detected by the methods employed in their study. Furthermore, the authors concluded that for airgun surveys conducted in rivers, the risk for fishes to be substantially affected by exposure is low as individuals would be exposed to only a few seismic impulses.

A study of auditory sensitivity in four species of tropical reef fishes following exposure to emissions from a 2,055 in^3 seismic airgun array showed that none of the four species, including the pinecone soldierfish (a species expected to have good hearing sensitivity) experienced any hearing sensitivity loss (i.e., TTS) following exposure to SEL up to 190 dB re 1 $\mu Pa^2 \cdot s$ (Hastings et al. 2008, Hastings and Miksis-Olds 2012). No detectable gross physiological damage was found in individuals from any of the seven species (McCauley and Kent 2012). The results of the hearing tests are consistent with the sound exposure guidelines proposed in Popper et al. (2014), which indicated that TTS may occur at SEL levels >186 dB re 1 $\mu Pa^2 \cdot s$, while other studies (Song et al. 2008, Popper and Hastings 2009a) indicate that TTS may occur at levels as high as SPL 205–210 dB re 1μPa (PK).

<u>Mortality</u>

There is no documented evidence that exposure to seismic airgun impulses causes mortality in fishes (Boeger et al. 2006, Normandeau Associates Inc 2012). Popper et al. (2016) investigated the possible levels of impulsive seismic airgun sound to which adult fish can be exposed without immediate mortality. They found that the two fish species in their study, with body masses in the 200–400 g range, exposed to a single-impulse of a maximum received level of either 231 dB re 1 μPa (PK) or 205 dB re 1 $\mu Pa^2 \cdot s$ (SEL), remained alive for 7 days after exposure and that the probability of mortal injury did not differ between exposed and control fish.

7.2.1.1.2. Offshore Pile Driving

<u>Stress</u>

In a comparative study by Radford et al. (2016), European seabass (*Dicentrarchus labrax*) showed heightened stress levels (indicated by elevated ventilation rates) in response to playbacks of recordings of pile driving and seismic surveys. This response diminished over time and animals were obviously desensitised after 12 weeks as they no longer showed signs of increased stress. Interestingly, no changes in growth or mortality were found in animals exposed to noise over long-term as compared to those reared with exposure to ambient-noise playback. The relevance of these findings may, however, be compromised by the fact that these experiments were conducted under laboratory conditions (Carroll et al. 2017).

In an *in situ* experiment, Debusschere et al. (2016) exposed juvenile European sea bass to offshore pile driving impulses. Their results demonstrated acute stress responses expressed by significant changes in secondary stress indicators (oxygen consumption rate and body lactate concentrations), which resulted in a temporary reduction of fitness.

<u>Behavioural Responses</u>

The published information on behavioural responses of fishes to pile driving sound is relatively scarce. Ruggerone et al. (2008) conducted a behavioural response study in juvenile Coho salmon (*Oncorhynchus kisutch*) that were held in cages next to a pile driving operation in a harbour. No apparent change in behaviour during the pile driving was reported, as less than 10% of the fish exhibited a startle response during the first or subsequent hammer strikes of each pile.

In controlled exposure experiment, Mueller-Blenkle et al. (2010) exposed Atlantic cod and sole (*Solea solea*) held in two large (40 m) net pens located in a quiet bay to playbacks of pile driving noise. They tracked their movements visually and quantified both the received sound pressure level and particle motion. Sole showed an increase in swimming speed at received peak sound pressure levels (PK) of 144–156 dB re 1µPa, and cod exhibited significant freezing response at onset and cessation of playback at received peak sound pressure levels of 140–161 dB re 1 µPa (particle motion was determined to be between 6.51×10^{-3} m/s² peak and 8.62×10^{-4} m/s² peak). The authors report a high variability in behavioural reactions across individuals and a decrease of response with multiple exposures.

In a sound playback experiment in an enclosed, quiet, coastal sea lough, Hawkins et al. (2014) exposed free-living pelagic fish to sound playback of synthetic, low-frequency, impulsive sounds, mimicking some of the features of sounds produced by pile drivers and seismic airguns. Behavioural responses of fishes were observed with a sonar/echo sounder. The fishes they encountered were predominantly sprat and Atlantic mackerel (*Scomber scombrus*) and were not accustomed to heavy disturbance from shipping and other intense sound sources. Following a short latency, sprat schools reacted to sound exposure with lateral dispersal, taking them outside the sonar beam. The fish often then reappeared at a greater depth recombined into a school. Mackerels responded by dispersing and/or a rapid depth change. The lowest received sound pressure level (PK-PK) eliciting a response in free-living sprat was 140 dB re 1 µPa, while mackerel responded to a received sound pressure level of 143 dB re 1 µPa. There was an increase in the proportion of sprat and mackerel schools responding to sound playback with increasing sound levels. The 50% response level for sprat was at a received sound pressure level (PK-PK) of 163.2 dB re 1 µPa, for mackerel schools the 50% level was reached at a peak-to-peak sound pressure level (PK-PK) of 163.3 dB re 1 µPa.

TTS

Casper et al. (2013) used a specially designed wave tube to expose hybrid striped bass (white bass *Morone chrysops* × striped bass *Morone saxatilis*) and Mozambique tilapia (*Oreochromis mossambicus*) to pile driving sounds and investigated the effects on hair cells. Exposure to 960 pile driving strikes at SEL_{24h} levels of 210–216 dB re 1 µPa²·s caused barotraumas in both species. Hair cells loss, in contrast, was only found at significant levels after exposure to the highest sound level in some striped bass and in a single tilapia.

Injury and Mortality

Casper et al. (2012) showed that fishes can recover from less severe injuries under laboratory conditions, suggesting that minor injuries do not inevitably lead to mortality. Nevertheless, in open waters, minor injuries have the potential to reduce the animal's fitness to the extent that its ability to find food decreases and its risk of being predated increases (Halvorsen et al. 2011, 2012b).

Mortality is either a direct effect of barotrauma (in the case of severe injury) or indirect if an animal is moderately injured. Halvorsen et al. (2011, 2012a, 2012b) exposed different fish species in a well-controlled acoustic environment (using a wave tube) to signals replicated from actual pile driving operations and found that the extent of injury increased with sound exposure levels and number of pile driving strikes. Their results demonstrated that an appropriate metric for guidelines may be a combination of the single strike SEL (SEL_{ss}) and the number of strikes that are used to yield the SEL value, with the understanding that at the same SEL value, higher SEL_{ss} and fewer strikes can result in the same onset of effects as a lower SEL_{ss} and more strikes (Popper et al. 2014).

Data on sound-induced direct mortality in fishes are scarce and mainly related to underwater explosions (Popper and Hastings 2009b). Observations conducted during pile driving activities showed that fish within a few metres of driving a large pile were killed (Caltrans 2001, 2004), but no data from these studies document the sound levels to which the fish were exposed or the extent of exposure before mortality occurred. At greater distances from pile driving activities, data from caged fish show no mortality and no damage that can be clearly associated with pile driving activities (Abbott et al. 2005, Nedwell et al. 2006, Ruggerone et al. 2008, Caltrans 2010b, 2010a, Houghton et al. 2010).

7.2.1.2. Non-Impulsive Sound Sources

7.2.1.2.1. Offshore Drilling

No scientific information is available on the potential of noise-induced effects on fishes following exposure to sound emitted by offshore drilling.

7.2.1.2.2. Vessels

Boat noise represents a chronic source of harassment for fish species (Popper 2003), whose communication is mainly based on low-frequency sound signals (Ladich and Myrberg 2006, Myrberg and Lugli 2006).

Stress

Wysocki et al. (2006) showed that boat noise can induce endocrine stress response in fish. Radford et al. (2016) compared the reaction of European seabass (*Dicentrarchus labrax*) to various types of sound, but found no signs of elevated stress in response to playbacks of recordings of ship passes. Nedelec et al. (2016) showed the same physiological responses in reef-associated fish after exposure to short-term exposure to vessel noise. Interestingly, these responses were diminished when the exposure continued (up to 2 weeks of repeated exposure). This desensitisation effect indicates that extrapolating results from short-term studies may lead to overestimating effects. Purser et al. (2016) exposed European eels (*Anguilla anguilla*) to playbacks of ambient coastal noise and coastal noise with passing ships. They found that juveniles in good condition do not respond differently to playbacks of ambient coastal noise and coastal noise with passing ships. In those individuals with poor body condition, by contrast, the additional noise of ship passes caused an increase in ventilation rate and a decrease in startling response to a looming predatory stimulus, thus providing evidence that noise effects can be condition-dependent.

Recent studies show that boat noise can induce endocrine stress response (Wysocki et al. 2006), diminish hearing ability, and mask intra-specific relevant signals in exposed fish species (Scholik and Yan 2002, Amoser et al. 2004b, Vasconcelos et al. 2007, Codarin et al. 2009). In addition, vessel noise can provoke short-term changes in the spatial position and group structure of pelagic fish in the water column (Buerkle 1973, Olsen et al. 1983, Schwarz and Greer 1984, Engås et al. 1995, Soria et al. 1996, Vabø et al. 2002, Mitson and Knudsen 2003, Ona et al. 2007, Sarà et al. 2007).

Auditory Masking

Scholik and Yan (2001), Vasconcelos et al. (2007), and Codarin et al. (2009) demonstrated masking effects due to vessel noise in several marine fish families. They measured decreased hearing sensitivities between 10 dB and more than 30 dB in the presence of vessel noise.

Codarin et al. (2009) investigated the effects of ambient and ship noise on representatives of three vocal fish families with different hearing abilities. In their laboratory study, they found that the noise emanating from recreational shipping substantially masked the auditory perception in these fish species, with a pronounced effect on the frequencies used for communication.

Stanley et al. (2017) modelled the effective communication range in Atlantic cod and haddock at three spawning locations. These areas are characterised by elevated levels of anthropogenic underwater sound, particularly due to commercial shipping. They found near constant high levels of low-frequency sound and consequentially a reduction in the communication space during times of high vocalisation activity for these fish species.

Behavioural Responses

Fish can respond to approaching vessels by diving towards the seafloor or by moving horizontally out of the vessel’s path, with reactions often initiated well before the vessel reaches the fish (Ona et al. 2007, Berthe and Lecchini 2016). The avoidance of vessels by fish has been linked to the high levels of infrasonic and low-frequency noise (>10 to 1000 Hz) emitted by the ships. Accordingly, it was suggested that silent ships have a higher chance of encountering more fish than noisier ones (De Robertis et al. 2010). This assumption was initially contradicted when two research vessels were compared with regard to their effect on schooling herring (Ona et al. 2007). The authors found that the reaction initiated by the silent vessel was stronger and more prolonged than the one initiated by the conventional vessel. In a comment to this publication, Sand et al. (2008) pointed out that fish are highly sensitive to particle acceleration and that the cue, in this case, may have been low-frequency particle acceleration caused by displacement of water by the moving hull in the near field of the vessel. This fact would explain the stronger response to the larger noise-reduced vessel in the study by Ona et al. (2007), which would have displaced more water as it approached.

Nedelec et al. (2016) investigated the response of reef-associated fish by exposing them in their natural environment to playback of motorboat noise. They found that juvenile fish increased hiding and ventilation rate after a short-term boat noise playback, but responses diminished after long-term playback thus indicating habituation to sound exposure over longer durations. These results were corroborated by Holmes et al. (2017) who also observed short-term behavioural changes in juvenile reef fish after exposure to boat noise as well as desensitisation over longer exposure periods.

TTS

A single study reported temporary threshold shift caused by exposure to vessel noise: Scholik and Yan (2001) exposed fathead minnows (*Pimephales promelas*) for two hours to sound playback recorded from small boats at a level of 142 dB re 1 μPa. They measured noise-induced threshold shift (NITS) of 7.8–13.5 dB at frequencies between 1–2 kHz, the most sensitive hearing range of this species.

7.3. Sea Turtles

7.3.1.1. Impulsive Sound Sources

Based on physiology, it is likely that TTS can occur in sea turtles as it does in other vertebrates. However, there is no robust information on the susceptibility of sea turtles to noise-induced effects to confirm this hypothesis. Injury or mortality have not been reported to have occurred in turtles as a result of noise emissions during seismic surveys. Because of their rigid external anatomy, it is possible that sea turtles are highly protected from impulsive sound effects (Popper et al. 2014).

7.3.1.1.1. Seismic Airguns

Few data exist on the effects of seismic airgun activity on sea turtles. Avoidance responses of sea turtles to low frequency tones have been demonstrated in caged animals (Lenhardt 1994). O'Hara and Wilcox (1990) found that sea turtles in a canal would avoid an area with an airgun, although the received level at the sea turtles was not measured. Moein et al. (1995) monitored the behaviour of penned loggerhead turtles to airguns firing at 175–179 dB re 1 μPa at 1 m. Avoidance to the airguns was observed at first exposure, but the sea turtles habituated to the sound over time. Behavioural responses by sea turtles, including rising to the surface and altered swimming patterns, have been elicited in caged animals exposed to an airgun at received levels of 166 dB (rms) re 1 μPa (McCauley et al. 2000). Weir (2007) reported no obvious behavioural avoidance by several species of sea turtle at the sea surface to a seismic survey as recorded by ship-based observers, although fewer turtles were seen at the surface when the airguns were firing.

There is not information on onset levels for TTS, injury or mortality of sea turtles from exposure to seismic airgun signals. It is likely that sea turtles would be subject to recoverable injury or TTS from exposure to seismic airgun signals; it is also possible that these signals could lead to direct or indirect mortality in sea turtles that are very close to the source, although preliminary data suggest that sea turtles are highly resistant to high intensity explosives (Ketten et al. 2005), making it likely that they would also be resistant to damage from seismic airguns. Accordingly, Popper et al. (2014) adopted onset levels for fish that do not hear well assuming that these would be conservative for sea turtles.

7.3.1.1.2. Offshore Pile Driving

No scientific information is available on the potential of noise-induced effects on sea turtles following exposure to sound emitted by offshore pile driving.

7.3.1.2. Non-Impulsive Sound Sources

No scientific information is available on the potential of noise-induced effects on sea turtles following exposure to non-impulsive sounds such as emitted by vessel operations or offshore drilling.

7.4. Marine Mammals

Marine mammals in general and cetaceans (whales, dolphins and porpoises) in particular received most scientific attention of all marine taxonomic groups with regard to the potential noise-induced effects. This is reflected in the larger volume of scientific literature on the various relevant aspects. However, due to the complexity of cause-effect relationships in this context, the elusive lifestyle of cetaceans and the relative difficulty for conducting well controlled experiments on (most of) these species the overall assessment remains difficult and incomplete. The following sections provide an overview of the existing knowledge and understanding of the potential noise-induced effects in cetaceans. Like for the other marine taxa, this is a quickly evolving field of ongoing research.

7.4.1. Stress

The available literature indicates that marine mammals increase the secretion of endocrine hormones and alter their cardiovascular function following relatively intense noise exposure in some cases.

7.4.1.1. Impulsive Sound Sources

7.4.1.1.1. Seismic Airguns

Non-auditory physiological effects do include changes in stress-related hormone levels and blood cell count (aldosterone and monocytes) levels in bottlenose dolphins; epinephrine, norepinephrine, and dopamine levels in beluga exposed to sounds from a seismic watergun (e.g., studies of beluga exposed to sounds from a seismic watergun in Romano et al. 2004).

7.4.1.1.2. Offshore Pile Driving

No scientific information is available specific for stress responses to exposure to sound from impact pile driving.

7.4.1.2. Non-Impulsive Sound Sources

No scientific information is available specific for stress responses to exposure to non-impulsive sounds as generated by vessel operations and offshore drilling.

7.4.2. Behaviour

7.4.2.1. Impulsive Sound Sources

7.4.2.1.1. Seismic Airguns

For exposure to pulsed sounds specifically, there is evidence that the behavioural state of baleen whales combined with their proximity to seismic sources affects how the whales react to the sounds (McCauley et al. 1998a, McCauley et al. 1998b, Gordon et al. 2003). Several species of baleen whales have exhibited avoidance behaviour to sounds from seismic surveys (Richardson et al. 1995), including bowhead whales (*Balaena mysticetus*) avoiding distant seismic airguns at received levels of SPL of 120–130 dB re 1 µPa during fall migration (Richardson et al. 1999). Feeding bowhead whales in the summer were more tolerant to airgun sounds—avoiding airguns only when received levels reached 152–178 dB re 1 µPa, about 40 dB higher than avoidance levels of the same population of migrating whales (Richardson et al. 1995). McDonald et al. (1995) observed that a blue whale stopped vocalising when within 10 km of an active seismic vessel.

Humpback whales tended to avoid seismic surveys with resting females diverting to remain 7–12 km away, though males were occasionally attracted to the sounds (McCauley et al. 2000b). During the first 72 h of a 10-day seismic survey, fin whales appeared to move away from the airgun array, with apparent displacement persisting at least 14 days beyond the 10-day duration of seismic airgun activity (Castellote et al. 2012). Migrating humpback whales avoided a 3130 in^3 commercial seismic airgun array and responded with decreased dive time, elevated respiration rates, increased breaching rates, decreased tail and pectoral fin slapping (Dunlop 2016), and reduced swim speed (Dunlop et al. 2017a). These behavioural responses were lessened or absent with smaller array volumes, though the migrating humpback whales avoided the vessels and their associated seismic sources (Dunlop et al. 2015, Dunlop et al. 2016). The behavioural response studies conducted by Dunlop et al. (2017b, 2018) suggest that proximity of the seismic airgun vessel and received level are important factors in triggering a response in humpback whales. Their results indicate that the size of the source is not a significant factor in predicting an avoidance response, nor the received level alone. Instead, it seems to be a combination of received level and proximity to the airgun source, in that for both aspects a threshold must be exceeded to trigger a greater magnitude of response. Similar to these findings, DeRuiter et al. (2013) reported that a beaked whale (*Ziphius cavirostris*) responded to nearby playback of naval sonar but not to signals from a distant real source.

Sperm whales in the Gulf of Mexico (GoM), where seismic surveys have been conducted nearly continuously for decades, were found to maintain their behaviour state when subjected to seismic sound sources, suggesting habituation to this relatively loud sound source (Miller et al. 2009). Similar results have been observed in the Arctic, where no changes were recorded in typical sperm whale vocal patterns during feeding dives in proximity to seismic survey noise (Madsen et al. 2002). Conversely, sensitization to sound exposure can occur and would lead to an increased behavioural responsiveness. The Sperm Whale Seismic Study (SWSS) conducted controlled exposure experiments in the GoM to determine the direction of movement in eight tagged sperm whales over a series of 30 min intervals during pre-exposure, ramp-up, and full-array firing (Jochens et al. 2008). Results showed no horizontal avoidance to received airgun sounds of <150 dB re 1 µPa (SPL) and diving and foraging rates were affected only in one individual (longer resting period at the surface and diving immediately following the final airgun transmission).

In response to seismic airgun sounds, small toothed whales showed the strongest lateral spatial avoidance, baleen whales and killer whales showed more localised spatial avoidance, long-finned pilot whales (*Globicephala melas*) only showed a change in orientation, and sperm whales did not show any significant avoidance response (Stone and Tasker 2006). A report from US Bureau of Ocean Energy Management (BOEM; Barkaszi et al. 2012) showed each species group (all cetaceans, baleen whales, delphinids, and sperm whales) was sighted at significantly greater distances from the seismic vessel when the source was operating at full power compared with times when the source was turned off, suggesting spatial avoidance to the seismic source. Pirotta et al. (2014) found that the acoustic activity of harbour porpoises in the northeast of Scotland was positively related to distance from a seismic source vessel. Probable avoidance of active seismic sources by odontocetes is also suggested by analysis of the reports of observers on seismic vessels off the UK collated by the UK Joint Nature Conservation Committee (Stone 2003). In contrast to these reports of avoidance in some whales, other observations suggest that sperm whales show little response and are not excluded from habitat by seismic surveys (e.g., Rankin and Evans 1998).

7.4.2.1.2. Offshore Pile Driving

<u>Cetaceans</u>

Kastelein et al. (2013) documented behavioural responses of a captive harbour porpoise to playbacks of pile driving sounds in a controlled experiment. Their results showed that above a received SPL of 136 dB re 1 µPa the porpoise's respiration rate increased in response to the pile driving sounds. At higher levels, the porpoise also jumped out of the water more often. In another study on a captive harbour porpoise (Kastelein et al. 2018) documented that these animals are capable of maintaining an increased swim speed of 2 m^{s-1} throughout 30 min, when exposed to pile driving playbacks with an SEL_{ss} of 145 dB re 1 $\mu Pa^2 \cdot s$.

There is evidence to suggest that harbour porpoises can habituate and/or adapt to impulsive anthropogenic sound in their environment (Cox et al. 2001). Dähne et al. (2013) and Brandt et al. (2011), however, demonstrated avoidance of offshore pile driving activities by harbour porpoises over a distance of 20 km.

Pinnipeds

A study on the effects of pile driving on ringed seals (*Phoca hispida*) at Northstar Island, Alaska, did not show dramatic reactions to underwater pile driving impulses with received SPL of at least 150 dB re 1 µPa (Blackwell et al. 2004). A study conducted in the North Sea, however, shows that offshore pile driving can cause temporary, localized displacement of marine mammals; during construction of offshore wind farms, harbour seals (*Phoca vitulina*) have demonstrated displacement of up to 25 km from the centre of the pile driving site (Russell et al. 2016).

7.4.2.1.3. Other impulsive sources

A recent report by Southall et al. (2013) concluded that multibeam echosounders used in offshore energy development projects may have played a significant role in a mass stranding of melon-headed whales, most likely by affecting their behaviour (see Section 6.5). Behavioural responses by toothed whales are also documented for higher frequency (>10 kHz) sonar such as multibeam echosounders (Vires 2011, Quick et al. 2016, Cholewiak et al. 2017). Controlled behavioural response studies documented reduced foraging effort in response to pulsed 1–2 kHz sonar (Isojunno et al. 2016). Similar responses were also observed following playbacks of killer whale (i.e., potential predator) sounds (Curé et al. 2016, Isojunno et al. 2016).

7.4.2.2. Non-Impulsive Sound Sources

7.4.2.2.1. Offshore Drilling

There is limited information on behavioural responses of marine mammals to sound emitted from offshore drilling activities. Malme et al. (1984) exposed migrating grey whales (*Eschrichtius robustus*) to playbacks of sounds recorded from a drillship and a drilling platform. They documented onset of behavioural reactions (deflection from migration route, i.e. avoidance) for 10% of the observed animals at received SPL of 110 dB and 114 dB re 1 µPa, respectively; 50% of the animals reacted at received SPL of 117 dB re 1 µPa and 90% reacted at received SPL of 122 and >128 dB re 1 µPa, respectively.

Richardson et al. (1991) documented behavioural reactions of spring-migrating bowhead whales (*Balaena mysticetes*) to playback of recorded drilling sound near the arctic ice. The whales showed an increased turning frequency at a received SPL of 114 dB re 1 µPa and strong behavioural changes (without turning away from the projector) at received SPL of 124 dB re 1 µPa. The received SPL at their typical closest point of approach to the sound projector was 131 dB re 1 µPa.

Blackwell et al. (2017) recorded the underwater sound of offshore drilling with six arrays of directional recorders and identified and localised bowhead whale calls produced within 2 km of each recorder array using triangulation. The analysis showed that with increasing tone levels, bowhead whale calling rates initially increased, peaked, and then decreased. Increasing call repetition rates can be a viable anti-masking strategy, i.e. to compensate for decreased detectability of signals arising due to increased background noise. Meanwhile, as noise levels increase further, the benefits likely decreases because information transfer (i.e. communication) becomes increasingly less efficient and eventually impossible.

7.4.2.2.2. Vessels

Mysticetes

With regard to non-impulsive sounds such as those produced by ships, the review by Southall et al. (2007) found no or limited responses by low-frequency cetaceans to non-impulsive sound at received levels up to 120 dB re 1 µPa, but an increasing probability of avoidance and other behavioural responses.

Humpback whales off the Australian east coast exhibited great variation in behavioural responses to seismic survey vessels with the airguns turned off. While no behavioural change was seen in some trials, others revealed a decrease in dive duration, travel speed, and the number of breaches (Dunlop et al. 2015, Dunlop 2016, Dunlop et al. 2017a, Dunlop et al. 2017b, Dunlop et al. 2018). As pointed out above, their results indicate a combined factor of received sound level and proximity of sound sources (seismic airguns and vessel) influencing the onset and strength of the animals responses. Tsujii et al. (2018) found that humpback whales moved away from large vessels, while others noted changes in respiratory behaviour (Baker and Herman 1989, Frankel and Clark 2002) and a cessation of foraging activities (Blair et al. 2016). However, in a controlled exposure experiment using a tactical sonar as sound source, most humpback whales did not respond to sonar vessels with the sonar turned off (Sivle et al. 2016, Wensveen et al. 2017). The large number of studies on humpback whales and the resulting variety of documented responses demonstrate that context affects behaviour and cause-effect relationships are not fully understood yet.

North Atlantic right whales (*Eubalaena glacialis*) show no behavioural response to ship noise at all, or at least not to received SPL of 132–142 dB 1 µPa from large ships passing within 1 nm distance, nor to received SPL of 129–139 dB re 1 µPa (main energy between 50 and 500 Hz) from ship noise playback (Nowacek et al. 2004a).

Blair et al. (2016) found a reduced foraging effort (slower descent rates and fewer side-roll feeding events on sand lance fish per dive) in humpback whales with increasing received levels (RL) from ship traffic. A general connection between noise and foraging effort was established but no thresholds for onset of behavioural responses could be deduced from their results. In the Western Mediterranean Sea Campana et al. (2015) documented a much higher sightings rate of cetaceans in areas of low vessel density compared to heavily trafficked areas with one general exception, that is, fin whales and deep sea diving cetaceans generally avoided ships except for an area in the central Ligurian Sea.

<u>Odontocetes</u>

In the case of beaked whales, much effort has been spent on understanding the potential effects of ship-based sonar transmissions given coincident strandings and naval exercises (e.g., DeRuiter et al. 2013, Sivle et al. 2015, Kvadsheim et al. 2017). The effects of ship noise without sonars have been investigated less. Using passive acoustic monitoring and acoustic tags, ship noise at received SPL of approximately 135 dB re 1 µPa (0.1–45 kHz) affected beaked whale foraging by reducing both the horizontal area in which animals foraged and the number of successful prey captures (as indicated by the number of feeding buzzes recorded), with foraging efficiency reduced by >50% (Aguilar Soto et al. 2006, Pirotta et al. 2012). Similarly, fewer clicks were recorded of sperm whales (*Physeter macrocephalus*) during vessel passes (Azzara et al. 2013), and decreases in surface time, respiration interval, and the number of ventilations were reported in the presence of whale-watching boats (Gordon et al. 1992). A different study found no decrease of sperm whale acoustic detections in ship noise (André et al. 2017). Rather, an increase in sperm whale acoustic and visual detections was found near longline fishing vessels, and propeller cavitation noise (to be exact, changes in that noise corresponding to typical operational changes in longline fishing vessel speeds) was identified as the ‘dinner bell’ attracting sperm whales to depredate (Thode et al. 2007). Such diverse responses (avoidance, no response, and attraction) highlight the importance of context in assessments of underwater noise.

Lesage et al. (1999) revealed that belugas reduced their overall call rate in the presence of vessels but increased the emission and repetition of specific calls and shifted to higher frequency bands.

Killer whales (*Orcinus orca*) in British Columbia, Canada, and Washington State, USA, have recently received much attention with regards to impacts from ships, given the steady decline in their population size. Changes in behaviour (i.e., less foraging and increased surface-active behaviour), respiration, and swim speed and direction occurred at received SPL above 130 dB re 1 µPa (0.01–50 kHz), and the Lombard effect (i.e., increased source level and vocalization duration) has been reported in ship noise levels above 98 dB re 1 µPa (1–40 kHz) (Williams et al. 2002, Foote et al. 2004, Holt et al. 2009, Lusseau et al. 2009, Noren et al. 2009, Holt et al. 2011, Williams et al. 2014). This geographic area has seen a lot of ship noise recording, quantification, and impact modelling studies (e.g. Erbe 2002, Erbe et al. 2012, Erbe et al. 2014, Williams et al. 2015, Cominelli et al. 2018, Joy et al. 2019).

Beluga whales lost pod integrity in response to icebreakers, commenced rapid movement, asynchronous and shallow dives, and changed their vocal behaviour (i.e., vocalisation types) at received SPL of 94–105 dB re 1 µPa (20–1000 Hz), while narwhals changed their locomotion (i.e., exhibited more directed and slower movement, became motionless, and sank) and fell silent at received SPL of about 124 dB re 1 µPa (20–1000 Hz) (Cosens and Dueck 1988, Finley et al. 1990). Since the 1990s, beluga whale responses to boats and ships have been studied more extensively in the St. Lawrence Estuary, Canada. Here, beluga whales have shown increasing avoidance (i.e., increased dive duration and swim speed) with the number of boats, as well as other changes in both physical and acoustic behaviour (Blane and Jaakson 1994, Lesage et al. 1999). The Lombard effect has been demonstrated as an increase in source level, vocalisation rate, and frequency (i.e., shift to higher frequencies; Lesage et al. 1999, Scheifele et al. 2005).

Dolphins were displaced or changed their site occupancy in response to vessel traffic (Lusseau 2005, Bejder et al. 2006, Rako et al. 2013, Pirotta et al. 2015, Pérez-Jorge et al. 2016). They altered their movement patterns within an area in response to vessel traffic, with animals changing their direction of travel, beginning to travel erratically, or significantly increasing traveling speeds when approached by vessels (Au and Perryman 1982, Nowacek et al. 2001, Mattson et al. 2005, Lemon et al. 2006, Lusseau 2006, Christiansen et al. 2010, Marley et al. 2017b).

Groups of Pacific humpback dolphins (*Sousa chinensis*) that contained mother-calf pairs increased their rate of whistling after a boat transited the area (Van Parijs and Corkeron 2001). The authors postulated that vessel sounds disrupted group cohesion, especially between mother-calf pairs, requiring them to re-establish by vocal contact after boat noise masked their communication.

Marley et al. (2017a) found that Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) in Fremantle Inner Harbour (WA) significantly increased their average movement speeds in high vessel densities but only for some activity states. Behavioural budgets also changed in the presence of vessels, with animals spending more time travelling and less time resting or socialising.

Watercrafts can cause a shift in dolphin behavioural budgets, generally increasing time spent travelling whilst decreasing time spent resting and socializing (Lusseau 2003, Constantine et al. 2004, Stensland and Berggren 2007, Arcangeli and Crosti 2009, Steckenreuter et al. 2012, Marley et al. 2017b). Other changes in behaviour can include alterations to dive patterns, displays of breathing synchrony, and changes in inter-animal distances (Janik and Thompson 1996, Nowacek et al. 2001, Hastie et al. 2003, Kreb and Rahadi 2004, Stensland and Berggren 2007).

Polacheck and Thorpe (1990) noted that harbour porpoises tended to swim away from approaching vessels. Off the western coast of North America, Barlow (1988) observed that harbour porpoises within 1 km of a survey vessel moved rapidly out of its path. Teilmann et al. (2013) reported on a single observation of a fast ferry passing apparently very close to a harbour porpoise at high speed. When the vessel appeared in the recording, the animal ascended to the surface and ceased echolocation. When the received levels were above approximately 115 dB re 1µPa (SPL), the animal dove and speeded up.

Pinnipeds

A study using acoustic tags (DTAGs) that record sound and behaviour concurrently showed that harbour and grey seals (*Halichoerus grypus*) were exposed to vessel noise 2.2–20.5% of their time at sea (Mikkelsen et al. 2019). In response to vessel noise, a tagged seal changed its diving behaviour, switching quickly from a dive ascent to descent (Mikkelsen et al. 2019). This observation agrees with descriptions of changes in diving reported from a juvenile northern elephant seal (*Mirounga angustirostris*) (Fletcher et al. 1996, Burgess et al. 1998).

Sirenia

Manatees (*Trichechus spp*.) respond to approaching boats by often changing their orientation (heading or roll), depth, diving behaviour, behavioural state, and swimming speed (Nowacek et al. 2004b, Miksis-Olds et al. 2007b, Rycyk et al. 2018). Such responses to vessels were more pronounced for vessels in close proximity and travelling at speed (Nowacek et al. 2004b). Dugongs were also affected by close boat approaches and less likely to continue feeding when vessels travelled within 50 m (Hodgson and Marsh 2007). Manatees foraged in habitat with lower ambient noise (that included vessel noise below 1 kHz), particularly at times with less boat density (Miksis-Olds et al. 2007a). Playback experiments simulating different boats at different speeds approaching to within 10 m supported earlier behavioural response studies that manatees swam to deeper waters in the presence of boat noise (Nowacek et al. 2004b).

7.4.3. Masking

Masking reduces the communication space of marine mammals (Clark et al. 2009, Hatch et al. 2012). A calculation of reductions in communication range can be a useful proxy for impact. So far, a direct assessment and quantification of masking effects in wild animals has proven impossible (Tougaard et al. 2015). It depends on the positions of the signalling and the receiving animal relative to the sound source and to each other. In humpback whales, tonal and grunting sounds acting as contact calls between a mother and its calf were recorded at comparatively low levels (Videsen et al. 2017). While there is controversy about the validity of conclusions, such low levels would create a small communication space (<100 m) that, in turn, would be sensitive to increases in ambient noise.

Most studies related to masking effects in marine mammals have investigated the auditory parameters that are most relevant in this context, such as auditory sensitivity, frequency-tuning (critical bandwidth and critical ratio), auditory integration time, and critical interval.

Marine mammals employ various methods to compensate for masking sounds to a limited degree. They may increase the amplitude of their calls (referred to as the Lombard effect) or change spectral and temporal properties of vocalisations such as frequency content (Parks et al. 2011, Hotchkin and Parks 2013).

As ambient noise levels increase, killer whales have been known to increase the amplitude of their calls (Holt et al. 2009). Right whales increase the amplitude of their calls or react to the presence of noise by changing vocalisation properties such as frequency content (Parks et al. 2011, Hotchkin and Parks 2013). North Atlantic right whales produced calls with a higher average fundamental frequency and lowered their call rates in high noise conditions (Parks et al. 2007a, 2009).

Erbe et al. (2016b) reviewed the current knowledge on masking in marine mammals, summarising data on marine mammal hearing as they relate to masking and discussing masking release processes of receivers. The variability seen in auditory sensitivity (Section 5.1.4) indicates the variability seen with respect to auditory masking.

7.4.3.1. Impulsive Sound Sources

7.4.3.1.1. Seismic Airguns

Studies show North Atlantic right whales produced calls with a higher average fundamental frequency and lowered their call rate in high noise conditions (Parks et al. 2007a, 2009), whereas blue whales have been recorded increasing their rate of social calling in the presence of signals emitted during a seismic exploration survey (Di Iorio and Clark 2009).

Bowhead whales were found to increase their calling rate in response to seismic airgun signals at low levels (approximately 94 dB re 1 $\mu Pa^2 \cdot s$ SEL, integrated over 10 minutes) (Di Iorio and Clark 2009). However, when those signals exceeded approximately 127 dB re 1 $\mu Pa^2 \cdot s$ SEL, their calling rate began to decrease, and when it reached approximately 160 dB re 1 $\mu Pa^2 \cdot s$ SEL the whales stopped calling completely (Blackwell et al. 2015). Note that the levels were measured with a receiver within 2 km of the whales; therefore, the received levels at the whales are approximations.

Castellote et al. (2012) reported that male fin whales from two different subpopulations not only modified their song characteristics during increased ambient noise conditions but also left the area for an extended period during seismic airgun activity, not returning for 14 days.

Some whales continue calling in the presence of seismic pulses and whale calls often can be heard between the seismic pulses (Richardson et al. 1986, McDonald et al. 1995, Greene et al. 1999a, 1999b, Smultea et al. 2004, Holst et al. 2005b, 2005a, Holst et al. 2006, Dunn and Hernandez 2009, Holst et al. 2011, Nieukirk et al. 2012, Thode et al. 2012, e.g., Bröker et al. 2013, Cerchio et al. 2014, Sciacca et al. 2016).

Sperm whales ceased vocalising when exposed to pulses from a very distant seismic ship (Bowles et al. 1994). However, more recent studies of sperm whales found that they continued vocalising in the presence of seismic pulses (Madsen et al. 2002, Tyack et al. 2003, Smultea et al. 2004, Holst et al. 2006, Jochens et al. 2008, Holst et al. 2011, Nieukirk et al. 2012). Madsen et al. (2006a) noted that airgun sounds would not be expected to cause significant masking of sperm whale calls given the intermittent nature of airgun pulses. Dolphins and porpoises are also commonly heard vocalising while airguns are operating (Gordon et al. 2003, Smultea et al. 2004, Holst et al. 2005a, 2005b, Potter et al. 2007, Holst et al. 2011).

7.4.3.1.2. Offshore Pile Driving

Madsen et al. (2006b) concluded that impact pile driving impulses have little potential to mask the auditory perception of marine mammals (cetaceans and pinnipeds) due to the short duration and low duty cycle of individual pile driving impulses. The masking potential of impulsive sound can gradually increase over distance due to dispersion while SPL are decreasing due to spreading loss, thus reducing a potential masking effect.

7.4.3.2. Non-Impulsive Sound Sources

7.4.3.2.1. Offshore Drilling

There is no information on auditory masking effects of sound emitted from offshore drilling activities for marine mammals. Studies reporting masking effects caused by vessels noise (below) may provide insight into the potential masking effects caused by offshore drilling; however, extrapolating from one source to another can be done but dissimilarities in sound spectra have to be taken into account.

7.4.3.2.2. Vessels

<u>Mysticetes</u>

Studies show North Atlantic right whales produced calls with a higher average fundamental frequency and lowered their call rate in high noise conditions (Parks et al. 2007a, Parks et al. 2009), whereas blue whales have been recorded increasing their discrete audible calls during a seismic survey (Di Iorio and Clark 2009) and when ship sounds were nearby (Melcon et al. 2012).

Grey whales (*Eschrichtius robustus*) have a limited repertoire of low-frequency (40–4000 Hz) vocalisations, which overlap with vessel noise (Dahlheim et al. 1984, Moore and Ljungblad 2012, Dahlheim and Castellote 2016, Burnham et al. 2018). In the presence of ships and boats, grey whales increased their vocalisation rate, and at times of increased outboard engine noise, received levels from grey whales were higher (interpreted as an increase in source levels; Dahlheim 1987, Dahlheim and Castellote 2016).

Humpback whales in Glacier Bay National Park, AK, United States of America, are prone to high noise exposures from tourism vessels. They have been shown to increase the amplitude of their vocalizations by 0.8 dB for every 1.0 dB increase in ambient noise, while also vocalising less frequently (Frankel and Gabriele 2017, Fournet et al. 2018). Similarly, singing individuals near Chichi-jima Island ceased singing after a passenger-cargo vessel passed within 1400 m (Tsujii et al. 2018).

Blue whales increased the frequency of their discrete, audible calls if ships were nearby (Melcon et al. 2012).

<u>Odontocetes</u>

Bottlenose dolphins (*Tursiops truncatus*) produced more whistles when boats approached (Buckstaff 2004) and emitted lower frequency and longer whistles when interacting with dolphin-watching boats, particularly during foraging activities (May-Collado and Quiñones-Lebrón 2014). Furthermore, Luís et al. (2014) discovered that the mean overall call rates decreased significantly in the presence of operating vessels. These changes in call emission rates and temporary shifts in whistles characteristics may be a vocal response to the proximity of operating vessels, facilitating communication in this busy noisy estuary. Similarly, high-speed ferry noise has been demonstrated to have implications for harbour porpoise (Hermannsen et al. 2014). For killer whales (*Orcinus orca*), an increased source level and vocalization duration has been reported in the presence of ship noise levels above 98 dB re 1 µPa rms (1–40 kHz) (Foote et al. 2004, Holt et al. 2009, Holt et al. 2011).

Dolphins have been observed to alter their whistle characteristics, such as their frequency range, in elevated noise conditions or in the presence of vessels (Morisaka et al. 2005, May-Collado and Wartzok 2008, Papale et al. 2015, Heiler et al. 2016, Marley et al. 2017b). Changes to whistle duration have also been reported (May-Collado and Wartzok 2008, May-Collado and Quiñones-Lebrón 2014), as have increases in whistle production rates (Scarpaci et al. 2000, Van Parijs and Corkeron 2001, Buckstaff 2004); Guerra et al. 2014; Martins et al. 2018).

Aguilar-Soto et al. (2006) reported that noise from a passing vessel masked the ultrasonic vocalisations of a Cuvier's beaked whale and reduced the maximum communication range by 82% when exposed to a 15-dB increase in ambient sound levels at the vocalisation frequencies; the effective detection distance of the Cuvier's beaked whale's echolocation clicks was reduced by 58%.

Pinnipeds

Underwater noise from watercraft has the potential to mask or alter the communication of pinnipeds. Bagočius (2014) showed that grey seal vocalizations recorded underwater in captivity overlapped with the noise spectrum of a vehicle/passenger ship. Terhune et al. (1979) reported a decrease in the loudness of underwater harp seal (*Pagophilus groenlandicus*) vocalizations after the presence of a vessel was recorded acoustically near whelping sites in the Gulf of St. Lawrence. This may have reflected a change in seal vocalizations or the movement of seals away from the recording area (Terhune et al. 1979).

7.4.4. TTS/PTS

Noise-induced physical impacts from exposure to non-impulsive sound have not been directly observed or measured in free-ranging marine mammals. A number of studies have been conducted on marine mammals in controlled conditions to investigate noise-induced threshold shift phenomena. The experiments have focused on measuring TTS[4] exposed to intense tones and band-limited noise with various sound pressure levels, frequencies, durations, and temporal patterns. These studies have been performed with dolphins and belugas, and a harbour porpoise exposed to tones with durations ranging from 1 s to 1 h. Most of these studies employed non-impulsive exposures, though four studies used intermittent tones (Mooney et al. 2009, Finneran et al. 2010, Kastelein et al. 2014, Kastelein et al. 2015b). Tonal signals may be used to represent the effects of military sonars, fish finders, depth sounders, and other sources emitting steady-state, narrowband signals. The studies showed that the temporal pattern of noise exposure affects the resulting threshold shift and for intermittent noise, the quiet periods between noise exposures allow some recovery of hearing compared to noise that is continuously present with the same total SEL (Ward 1997, Finneran et al. 2007). For continuous exposures with the same SEL but different durations, the exposure with the longer duration will tend to produce higher levels of TTS.

Finneran (2015) and Finneran et al. (2017) provide reviews and a comprehensive assessment of the existing information on noise-induced TTS in marine mammals. These publications provided the basis for the most recent set of underwater noise regulations in the US (NMFS 2018).

7.4.4.1. Impulsive Sound Sources

In marine mammals, the onset level and growth of TTS (i.e. the increase of TTS with increasing sound exposure levels) is frequency specific, depends on the temporal pattern, duty cycle, and the hearing test frequency of the fatiguing stimuli (Finneran 2015, Finneran et al. 2017). Exposure to intense impulsive noise might be more hazardous to hearing than non-impulsive noise, and there is a positive relationship between exposure duration and the amount of TTS induced. TTS can accumulate across multiple exposures, but the resulting TTS will be less than the TTS from a single, continuous exposure with the same total SEL. Sounds generated by seismic airguns, pile driving and mid-frequency sonars have directly been tested and proven to cause noise-induced threshold shifts in marine mammals at high received levels. Finneran (2015) reviewed the current state of knowledge on TTS and PTS. TTS typically decreases in marine mammals relative to the logarithm of the increasing recovery time. There is, however, considerable individual difference in all TTS-related parameters between subjects and species tested so far.

PTS is considered injurious in marine mammals, but there are no published data on the sound levels that cause PTS in marine mammals. Regeneration of sensory cells, as known to occur in fishes, has

[4] No PTS has been performed on marine mammals.

not been documented for any marine or terrestrial mammal. Onset levels of PTS onset are typically extrapolated from TTS onset levels and assumed growth functions (Southall et al. 2007).

The role of the temporal pattern of sound on TTS in marine mammals has been studied in MF and HF cetaceans (Mooney et al. 2009, Finneran et al. 2010, Kastelein et al. 2014, Kastelein et al. 2015b).

7.4.4.1.1. Seismic Airguns

Cetaceans

Only a few studies have investigated TTS in marine mammals in response to exposure to impulsive sounds such as airgun impulses. Lucke et al. (2009) tested the effect of a single airgun on a male harbour porpoise. They documented onset of TTS at received (unweighted) SEL of 164 dB re 1 µPa^2·s. This equates to a (HF) weighted SEL_{24h} of 140 dB re 1 µPa^2·s (NMFS 2018). The main energy of the fatiguing stimulus (airgun pulse) was centred below 500 Hz, but a substantial amount of energy was also present at higher frequencies.

Kastelein et al. (2017b) exposed a harbour porpoise to 10 and 20 consecutive airgun impulses at received SEL_{24h} of 188–191 dB re 1 µPa^2·s with a mean shot intervals of around 17 seconds. TTS of ~4.4 dB was measured at 4 kHz.

Finneran (2015) tested the exposed three bottlenose dolphins to 10 impulses produced by a seismic airgun. The highest exposures were conducted at peak sound pressure levels (PK) of 210 dB re 1 µPa, peak-peak sound pressure levels (PK-PK) of 212 dB re 1 µPa, and cumulative (unweighted) SEL_{24h} of 195 dB re 1 µPa^2·s. This exposure induced 9 dB TTS in one animal at 8 kHz.

In other studies, bottlenose dolphins exposed to multiple airgun impulses up to 195 dB SEL did not experience any TTS (Finneran et al. 2015). Two of the three test animals were observed turning their heads away from the sound source, suggesting that they might be anticipating the next impulse and potentially self-mitigating the received levels (Finneran et al. 2015).

Pinnipeds

Two previously untested, pinniped species from the Arctic, a spotted seal (*Phoca largha*) and a ringed seals (*Pusa hispida*) were exposed to impulsive noise from a seismic airgun before their hearing sensitivity was measured with a psychoacoustic method at 100 Hz (Reichmuth et al. 2016). Even at a received unweighted SEL of up to 181 dB re 1 µPa^{2}s and peak-to-peak pressure level (PK-PK) of up to 207 dB re 1 µPa no evidence for TTS was found. The authors conclude that their findings confirm that existing regulatory guidelines in the US for single impulse noise exposures are conservative for seals.

7.4.4.1.2. Offshore Pile Driving

Cetaceans

In a study using playbacks of pile driving sounds, Kastelein et al. (2016) exposed harbour porpoises to a maximum single-strike unweighted broadband SEL of 145 dB re 1 µPa^{2}s and a cumulative SEL_{24h} of up to 187 dB re 1 µPa^2·s. TTS increased from 0 dB after 15 min exposure to 5 dB after 360 min exposure. Based on their results, they calculated an onset of TTS for this type of sound at a SEL_{24h} of ~175 dB re 1 µPa^2·s.

Kastelein et al. (2015a) tested the auditory tolerance of a harbour porpoise to playbacks of pile driving sounds. Using a psychoacoustic technique, they measured the animal’s hearing sensitivity at frequencies between 0.5 and 125 kHz for TTS. After one hour of exposure (2760 strikes) at single strike unweighted SEL 146 dB re 1 µPa^{2}s and a SEL_{24h} of 180 dB re 1 µPa^{2}s, TTS of 2.3 dB and 3.6 dB occurred at 4 kHz and 8 kHz, respectively, but at no other frequency tested. The recovery occurred within 48 min. The average cumulative, weighted SEL_{24h} from these exposures is approximately 144 dB re 1 µPa^2·s.

Pinnipeds

Kastelein et al. (2018) exposed harbour seals in a controlled study to low received playback levels of pile driving impulses and documented TTS of 3.9 dB at 4 kHz after exposure over 360 minutes. The TTS onset level was found at an SEL of 192 dB re 1 µPa^{2}s.

7.4.4.2. Non-Impulsive Sound Sources

Acoustic emissions from offshore drilling and vessel operations have not been tested for their potential for causing TTS in marine mammals. In the absence of information for these types of acoustic signatures, conclusions on potential effects and thresholds can be drawn from research on TTS effects of other non-impulsive sounds such as (military) sonar signals, or from studies using tones or band-limited signals as acoustic stimuli.

7.4.5. Mortality

7.4.5.1. Impulsive Sound Sources

There is no direct evidence for the potential of seismic airgun and impact pile driving impulses to cause mortality in marine mammals. Exposure to noise from seismic surveys has been implicated in the deaths of two beaked whales in the Gulf of California in 2002 (Lamont-Doherty Earth Observatory survey); although no direct correlation has been proven it was considered to be the indirect cause of death of the marine mammals (Cox et al. 2006).

7.4.5.1.1. Other Sound Sources

The only evident case of an injury to a marine mammal caused by what can clearly be considered an impulsive underwater sound source was reported by Ketten et al. (1993). However, as the most likely sound source in this case was an underwater explosion of undefined charge weight and distance to the animals, the physical cause of the injury may have been the shock wave created by the explosion.

7.4.5.2. Non-Impulsive Sound Sources

There is no scientific information available on the potential of sound emitted by offshore drilling or vessel operations to cause mortality in marine mammals.

Glossary

Term	Definition
1/3-octave	One third of an octave. Note: A one-third octave is approximately equal to one decidecade (1/3 oct ≈ 1.003 ddec; ISO 2017).
1/3-octave-band	Frequency band whose bandwidth is one one-third octave. Note: The bandwidth of a one-third octave-band increases with increasing centre frequency.
90%-energy time window	The time interval over which the cumulative energy rises from 5 to 95% of the total pulse energy. This interval contains 90% of the total pulse energy. Symbol: T_{90}.
90% sound pressure level (90% SPL)	The root-mean-square sound pressure levels calculated over the 90%-energy time window of a pulse. Used only for pulsed sounds.
A-weighting	Frequency-selective weighting for human hearing in air that is derived from the inverse of the idealized 40-phon equal loudness hearing function across frequencies.
Absorption	The reduction of acoustic pressure amplitude due to acoustic particle motion energy converting to heat in the propagation medium.
Acoustic masking	Obscuring of sounds of interest by sounds at similar frequencies.
Ambient noise	All-encompassing sound at a given place, usually a composite of sound from many sources near and far (ANSI S1.1-1994 R2004), e.g., shipping vessels, seismic activity, precipitation, sea ice movement, wave action, and biological activity.
Attenuation	The gradual loss of acoustic energy from absorption and scattering as sound propagates through a medium.
Audiogram	A graph of hearing threshold level (sound pressure levels) as a function of frequency, which describes the hearing sensitivity of an animal over its hearing range.
Auditory frequency weighting (auditory weighting function, frequency-weighting function)	The process of band-pass filtering sounds to reduce the importance of inaudible or less-audible frequencies for individual species or groups of species of aquatic mammals (ISO 2017).
Azimuth	A horizontal angle relative to a reference direction, which is often magnetic north or the direction of travel. In navigation it is also called bearing.
Background noise	Total of all sources of interference in a system used for the production, detection, measurement, or recording of a signal, independent of the presence of the signal (ANSI S1.1-1994 R2004). Ambient noise detected, measured, or recorded with a signal is part of the background noise.
Bandwidth	The range of frequencies over which a sound occurs. Broadband refers to a source that produces sound over a broad range of frequencies (e.g., seismic airguns, vessels) whereas narrowband sources produce sounds over a narrow frequency range (e.g., sonar) (ANSI/ASA S1.13-2005 R2010).
Bar	Unit of pressure equal to 100 kPa, which is approximately equal to the atmospheric pressure on Earth at sea level. 1 bar is equal to 105 Pa or 1011 µPa.
Decibel (dB)	One-tenth of a bel. Unit of level when the base of the logarithm is the tenth root of ten, and the quantities concerned are proportional to power (ANSI S1.1-1994 R2004).
Frequency	The rate of oscillation of a periodic function measured in cycles-per-unit-time. The reciprocal of the period. Unit: hertz (Hz). Symbol: f. 1 Hz is equal to 1 cycle per second.
Functional hearing group	Groups of marine mammal species with similar hearing ranges. Commonly defined functional hearing groups include low-, mid-, and high-frequency cetaceans, phocid pinnipeds (in air and water) and otariid pinnipeds (in air and water).
Hearing threshold	The sound pressure level for any frequency of the hearing group that is barely audible for a given individual in the absence of significant background noise during a specific percentage of experimental trials.

Term	Definition
High-frequency cetacean	The functional cetacean hearing group that represents those odontocetes (toothed whales) specialized for hearing high frequencies.
Hertz (Hz)	A unit of frequency defined as one cycle per second.
Impulsive sound	Sound that is typically brief and intermittent with rapid (within a few seconds) rise time and decay back to ambient levels (NOAA 2013, ANSI S12.7-1986 R2006). For example, seismic airguns and impact pile driving.
Intermittent sound	A level of sound that abruptly drops to the background noise level several times during the observation period.
Kurtosis	A measure of the outliers in given distribution (or time-series) relative to their occurrence in a normal distribution.
Lombard effect	The Lombard effect (response) is an increase in the subject's vocal levels in response to increased noise levels. This functions to maintain an adequate signal-to-noise ratio at the position of the receiver when noise levels vary (Lombard 1911).
Low-frequency cetacean	The functional cetacean hearing group that represents mysticetes (baleen whales) specialized for hearing low frequencies.
Mid-frequency cetacean	The functional cetacean hearing group that represents those odontocetes (toothed whales) specialized for mid-frequency hearing.
Non-impulsive sound	Sound that is broadband, narrowband or tonal, brief or prolonged, continuous or intermittent, and typically does not have a high peak pressure with rapid rise time (typically only small fluctuations in decibel level) that impulsive signals have (ANSI/ASA S3.20-1995 R2008). For example, marine vessels, aircraft, machinery, construction, and vibratory pile driving (NIOSH 1998, NOAA 2015).
Odontocete	The presence of teeth, rather than baleen, characterizes these whales. Members of the Odontoceti are a suborder of cetaceans, a group comprised of whales, dolphins, and porpoises. This group includes sperm whales, killer whales, belugas, narwhals, dolphins, and porpoises.
Otariid	A common term used to describe members of the Otariidae, eared seals, commonly called sea lions and fur seals. Otariids are adapted to a semi-aquatic life; they use their large fore flippers for propulsion. Their ears distinguish them from phocids. Otariids are one of the three main groups in the superfamily Pinnipedia; the other two groups are phocids (true seals) and odobenids (walrus).
Particle motion, sound	The magnitude and direction of movement of particles making up the media due to presence of a sound wave. Particle motion is expressed as a vector quantifying movement such as displacement, velocity, or acceleration
Peak pressure level (PK)	The maximum instantaneous sound pressure level, in a stated frequency band, within a stated period. Also called zero-to-peak pressure level. Unit: decibel (dB).
Permanent threshold shift (PTS)	A permanent loss of hearing sensitivity caused by excessive noise exposure. PTS is considered auditory injury.
Phocid	A common term used to describe all members of the family Phocidae. These true/earless seals are more adapted to in-water life than are otariids, which have more terrestrial adaptations. Phocids use their hind flippers to propel themselves. Phocids are one of the three main groups in the superfamily Pinnipedia; the other two groups are otariids and walrus.
Pinniped	A common term used to describe all three groups that form the superfamily Pinnipedia: phocids (true seals or earless seals), otariids (eared seals or fur seals and sea lions), and odobenids (walrus).
Pressure, acoustic	The deviation from the ambient hydrostatic pressure caused by a sound wave. Also called overpressure. Unit: pascal (Pa). Symbol: ρ.
Scholte wave	An acoustic wave propagating at a fluid–solid interface (such as water-sediment) and decaying exponentially in both directions along the normal to its interface (Vinh 2013).

Term	Definition
Sound exposure level (SEL)	A cumulative measure related to the sound energy in one or more pulses. Unit: dB re 1 μPa²·s. SEL is expressed over the summation period (e.g., per-pulse SEL [for airguns], single-strike SEL [for pile drivers], 24-hour SEL).
Sound pressure level (SPL)	The decibel ratio of the time-mean-square sound pressure, in a stated frequency band, to the square of the reference sound pressure (ANSI S1.1-1994 R2004). For sound in water, the reference sound pressure is one micropascal (p_0 = 1 μPa) and the unit for SPL is dB re 1 μPa²: $L_p = 10 \log_{10}(p^2/p_0^2) = 20 \log_{10}(p/p_0)$ Unless otherwise stated, SPL refers to the root-mean-square (rms) pressure level. See also 90% sound pressure level and fast-average sound pressure level. Non-rectangular time window functions may be applied during calculation of the rms value, in which case the SPL unit should identify the window type.
Source level	The sound level measured in the far-field and scaled back to a standard reference distance of 1 metre from the acoustic centre of the source. Unit: dB re 1 μPa·m (pressure level) or dB re 1 μPa²·s·m (exposure level).
Temporary threshold shift (TTS)	Temporary loss of hearing sensitivity caused by excessive noise exposure.

Appendix A. Physical Characteristics of Underwater Sound

The following section provides a brief overview of the most important aspects and introduces the most relevant terms and metrics.

A.1. Sound Characteristics

Sound is a physical phenomenon consisting of minute vibrations that travel through a supporting medium, such as air or water. When the surface of a vibrating object (sound source) moves forward into the medium, it compresses the surrounding molecules, thereby creating a region of higher pressure. As the surface then moves back toward and past its neutral position, the molecules of the surrounding medium expand back and a region of lower pressure results. These cycles are called compressions and rarefactions, respectively (Figure A-1).

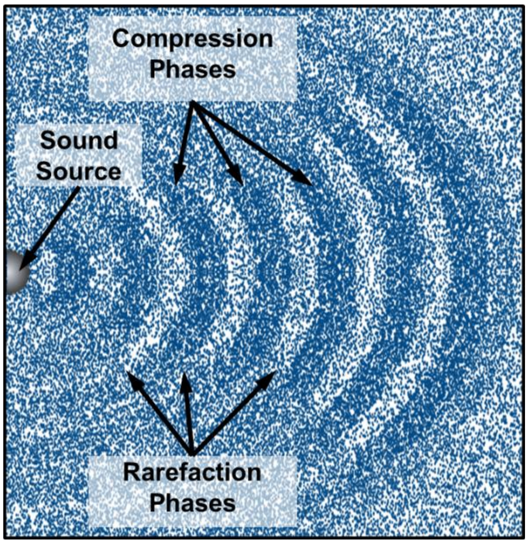

Figure A-1. Compression and rarefaction phases of a travelling sound wave.

The successive compressions and rarefactions result in sound waves. The speed at which these compressions and rarefactions travel away from the source depends on the compressibility and density of the medium and defines the speed of sound in that medium. Sound waves travel much faster in water than in air.

Sound is generally described in terms of frequency (or pitch), intensity, and temporal properties (e.g., short or long in duration, impulsive and non-impulsive). The following text provides a general description of these terms. For more details, there are several publications and books that provide detailed overviews of underwater acoustics, such as Richardson et al. (1995) and Au and Hastings (2008a), and some internet sources such as the Discovery of Sound in the Sea (DOSITS 2019), which is a highly recommended source of information on the subject.

Frequency is a measure of how many times the crest of a sound pressure wave passes a fixed point over the duration of a second; it is measured in Hertz (Hz). Some mysticetes (baleen whales) produce and may hear sounds below 20 Hz, while odontocetes (toothed whales) produce and hear sounds at frequencies much higher (up to 180 kHz for some species).

Sound intensity is defined as the acoustic power per unit area. The intensity, power, and energy of a sound wave are proportional to the average of the squared pressure. Measurement instruments and most receivers (humans, animals) sense changes in pressure, which is measured in Pascals (Pa). While pressure changes due to sound waves can be measured in Pascals, they are more commonly expressed in decibels (dB). The decibel is a logarithmic scale that is based on the ratio of the sound pressure relative to a standard reference pressure. The logarithmic decibel scale is used to allow comparison of extremely large sound pressure differences between sources.

Different standard reference pressures are used for airborne sounds and underwater sounds. The airborne standard pressure reference is $p_{ref(air)}$ = 20 micropascals (µPa), while the underwater standard reference pressure is $p_{ref(water)}$ = 1 µPa. The formula used to convert a pressure p measured in micropascals to sound pressure level *P* measured in dB is *P* = 20 log10 [p/p_{ref}]. Because of the logarithmic nature of the decibel scale, sound levels cannot be added or subtracted directly. If a sound's pressure is doubled, its sound level increases by 6 dB, regardless of the initial sound level.

A.2. Pressure Related Acoustic Metrics

Underwater sound pressure amplitude is measured in decibels (dB) relative to a fixed reference pressure of p_0 = 1 µPa. Because the perceived loudness of sound, especially pulsed sound such as from seismic airguns, pile driving, and sonar, is not generally proportional to the instantaneous acoustic pressure, several sound level metrics are commonly used to evaluate sound and its effects on marine life. Here we provide specific definitions of relevant metrics used in the accompanying report. Where possible, we follow the American National Standard Institute and International Organization for Standardization definitions and symbols for sound metrics (ISO 2017, e.g., ANSI R2013), but these standards are not always consistent.

The zero-to-peak sound pressure, or peak sound pressure (PK or $L_{p,\mathrm{pk}}$; dB re 1 µPa), is the decibel level of the maximum instantaneous acoustic pressure in a stated frequency band attained by an acoustic pressure signal, $p(t)$:

$$L_{p,\mathrm{pk}} = 10\log_{10}\frac{\max|p^2(t)|}{p_0^2} = 20\log_{10}\frac{\max|p(t)|}{p_0} \qquad \text{(A-1)}$$

PK is often included as a criterion for assessing whether a sound is potentially injurious; however, because it does not account for the duration of an acoustic event, it is generally a poor indicator of perceived loudness.

The peak-to-peak sound pressure (PK-PK or $L_{p,\mathrm{pk\text{-}pk}}$; dB re 1 µPa) is the difference between the maximum and minimum instantaneous sound pressure, possibly filtered in a stated frequency band, attained by an impulsive sound, $p(t)$:

$$L_{\mathrm{p,pk\text{-}pk}} = 10\log_{10}\frac{[\max(p(t)) - \min(p(t))]^2}{p_0^2} \qquad \text{(A-2)}$$

The sound pressure level (SPL or L_p; dB re 1 µPa) is the root-mean-square (rms) pressure level in a stated frequency band over a specified time window (T; s). It is important to note that SPL always refers to a rms pressure level and therefore not instantaneous pressure:

$$L_{\mathrm{p}} = 10\log_{10}\left(\frac{1}{T}\int_T g(t)\,p^2(t)\,dt \Big/ p_0^2\right) \qquad \text{(A-3)}$$

where $g(t)$ is an optional time weighting function. In many cases, the start time of the integration is marched forward in small time steps to produce a time-varying SPL function. For short acoustic events, such as sonar pulses and marine mammal vocalizations, it is important to choose an appropriate time window that matches the duration of the signal. For in-air studies, when evaluating the perceived loudness of sounds with rapid amplitude variations in time, the time weighting function $g(t)$ is often set to a decaying exponential function that emphasizes more recent pressure signals. This function mimics the leaky integration nature of mammalian hearing. For example, human-based fast time-weighted SPL ($L_{p,\mathrm{fast}}$) applies an exponential function with time constant 125 ms. A related simpler approach used in underwater acoustics sets $g(t)$ to a boxcar (unity amplitude) function of width 125 ms; the results can be referred to as $L_{p,\mathrm{boxcar\ 125ms}}$. Another approach, historically used to evaluate SPL of impulsive signals underwater, defines $g(t)$ as a boxcar function with edges set to the times corresponding to 5% and 95% of the cumulative square pressure function encompassing the duration of an impulsive acoustic event. This calculation is applied individually to each impulse signal, and the results have been referred to as 90% SPL ($L_{p,90\%}$).

The sound exposure level (SEL or L_E; dB re 1 µPa²·s) is the time-integral of the squared acoustic pressure over a duration (T):

$$L_E = 10\log_{10}\left(\int_T p^2(t)\,dt \Big/ T_0 p_0^2\right) \quad \text{(A-4)}$$

where T_0 is a reference time interval of 1 s. SEL continues to increase with time when non-zero pressure signals are present. It is a dose-type measurement, so the integration time applied must be carefully considered for its relevance to impact to the exposed recipients.

SEL can be calculated over a fixed duration, such as the time of a single event or a period with multiple acoustic events. When applied to pulsed sounds, SEL can be calculated by summing the SEL of the N individual pulses. For a fixed duration, the square pressure is integrated over the duration of interest. For multiple events, the SEL can be computed by summing (in linear units) the SEL of the N individual events:

$$L_{E,N} = 10\log_{10}\sum_{i=1}^{N} 10^{\frac{L_{E,i}}{10}} \quad \text{(A-5)}$$

Because the SPL(T_{90}) and SEL are both computed from the integral of square pressure, these metrics are related numerically by the following expression, which depends only on the duration of the time window T:

$$L_p = L_E - 10\log_{10}(T) \quad \text{(A-6)}$$

$$L_{p90} = L_\text{E} - 10\log_{10}(T_{90}) - 0.458 \quad \text{(A-7)}$$

where the 0.458 dB factor accounts for the 10% of pulse SEL missing from the SPL(T_{90}) integration time window.

Energy equivalent SPL (L_eq; dB re 1 µPa) denotes the SPL of a stationary (constant amplitude) sound that generates the same SEL as the signal being examined, $p(t)$, over the same time period, T:

$$L_\text{eq} = 10\log_{10}\left(\frac{1}{T}\int_T p^2(t)\,dt \Big/ p_0^2\right) \quad \text{(A-8)}$$

The equations for SPL and the energy-equivalent SPL are numerically identical. Conceptually, the difference between the two metrics is that the SPL is typically computed over short periods (typically of one second or less) and tracks the fluctuations of a non-steady acoustic signal, whereas the L_eq reflects the average SPL of an acoustic signal over time periods typically of one minute to several hours.

If applied, the frequency weighting of an acoustic event should be specified, as in the case of weighted SEL (e.g., $L_{E,\text{LF,24h}}$) or auditory-weighted SPL ($L_{p,\text{ht}}$). The use of fast, slow, or impulse exponential-time-averaging or other time-related characteristics should also be specified.

In the present report, audiogram-weighted, fast-averaged SPL ($L_{p,\text{ht,F}}$) is defined by the exponential function from Plomp and Bouman (1959):

$$L_{p,\text{ht}} = L_{E,\text{ht,per-pulse}} - 10\log_{10}(d/0.9)\,,$$
$$L_{p,\text{ht,F}} = L_{p,\text{ht}} + 10\log_{10}\frac{1-e^{-d/\tau}}{1-e^{-T/\tau}} \quad \text{(A-9)}$$

where d is the duration in seconds, τ is the time constant of 0.125 s representing marine mammal auditory integration time, $L_{p,\text{ht}}$ is the audiogram-weighted SPL over pulse duration, and T is the pulse repetition period. This metric accounts for the hearing sensitivity of specific species through frequency weighting, and results in reduced perceived loudness (i.e., sensation level) for pulses shorter than auditory integration time (τ).

A.3. Kurtosis

Popper and Hawkins (2019) proposed kurtosis[5] as a metric to distinguish impulsive sounds in the studies of fish and invertebrates. Martin et al. (2020) compared various types of impulsive and non-impulsive sounds in terms of their kurtosis, and the results strongly support using kurtosis for quantifying impulsiveness for future assessments and revised underwater noise regulations. The results also show that by applying this metric, it becomes irrelevant for assessing hearing impairment if impulsive signals seemingly merge into non-impulsive signals over distance due to dispersion as their kurtosis remains high (i.e., an indicator for impulsiveness). However, this aspect is a field of ongoing research, and while kurtosis is an established criterion in human audiometry, no studies have applied it to date to marine species; it therefore remains unclear if kurtosis is the ultimate criterion for determining the impulsiveness of acoustic signals for these taxa.

A.4. Particle Motion

Since sound is a mechanical wave, it can also be measured in terms of the vibratory motion of fluid particles. Particle motion can be measured in terms of three different (but related) quantities: displacement, velocity, or acceleration. Acoustic particle velocity is the time derivative of particle displacement, and likewise acceleration is the time derivative of velocity. The most relevant particle motion metrics with regard to potential effects on marine fauna are acceleration and velocity.

The particle velocity (v) is the physical speed of a particle in a material moving back and forth in the direction of the pressure wave. It can be derived from the pressure gradient and Euler's linearized momentum equation where ρ_0 is the density of the medium:

$$v = -\int \nabla p(t) dt / \rho_0 \,. \qquad \text{(A-10)}$$

The particle acceleration (a) is the rate of change of the velocity with respect to time, and it can be obtained from A-10 as

$$a = \frac{dv}{dt} = -\frac{\nabla p(t)}{\rho_0} \qquad \text{(A-11)}$$

Unlike sound pressure, particle motion is a vector quantity, meaning that it has both magnitude and direction: at any given point in space, acoustic particle motion has three different time-varying components (x, y, and z). Given the particle velocity in the x, y, and z, directions, v_x, v_y, and v_z, the particle velocity magnitude $|v|$ is computed per the Pythagorean equation:

$$|v| = \sqrt{v_x + v_y + v_z} \qquad \text{(A-12)}$$

The magnitude of particle acceleration is calculated similarly from the particle acceleration in the x, y, and z directions.

[5] Kurtosis is a measure of the outliers in given distribution (or time-series) relative to their occurrence in a normal distribution. Kurtosis is not a measure of sharpness or roughness of an acoustic signal.

Attachment 12 Greenhouse Gas Emissions Quantification

Santos Dorado Development Projected Emissions Inventory

Revised final report

Santos WA Energy Ltd

3 March 2022 | 125908 | v3

Executive summary

Santos' proposed Dorado Development will be located in the Bedout Basin offshore of north-west Western Australia. The proposed Dorado Development includes a 16 slot well head platform with a floating production storage and offloading (FPSO) facility handling oil and condensate stabilisation, storage and offloading, water treatment for disposal, gas dehydration, gas compression and reinjection. Full production is anticipated in 2026 and covers a 20-year period. Our assessment is based on a total production volume of 350 million barrels (MMbbl) of oil from the Dorado Development which includes future tiebacks[1] from nearby fields (Project Area).

As part of the regulatory requirements, and to improve the understanding of the associated environmental impacts and risks, Santos has prepared an Offshore Project Proposal (OPP) for assessment by the National Offshore Petroleum Safety and Environmental Management Authority (NOPSEMA). Energetics has assisted Santos with quantifying the atmospheric emissions from the Dorado Development, as an input to the OPP. This report sets out the key findings of the projected emissions inventory of the proposed Dorado Development.

Scope of our assessment

The boundary of our assessment is limited to the production and onshore processing and use of 350 MMbbl of oil from the Dorado Development including future tiebacks from neighbouring fields from currently identified prospects in the Project Area. The assessment assumes that the oil is processed onboard an FPSO installation operating for 20 years at full capacity and includes emissions from drilling and installation of wellhead platforms (WHPs) and facilities, as well as commissioning and decommissioning of the FPSO. It is assumed that 100% of the oil product will be shipped to Kobe, Japan for refining. Transport from the receiving Kobe port to the refinery is assumed to be negligible. The final products from the refining process were assumed to follow the typical slate from the processing of Cossack crude (given that there are currently no estimates of the refining slate for Dorado fluids), and 100% of the final product is assumed to be combusted.[2]

Dorado Development's atmospheric emissions profile

Emissions from the Dorado Development will include greenhouse gases (GHGs) and other atmospheric emissions. To assess GHG emissions, Energetics relied on guidance from the GHG Protocol (GHGP) Corporate Accounting and Reporting Standard.[3] The GHGP classifies GHG emissions into three 'scopes'. For this assessment, and aligned with the GHGP, Scope 1 emissions include all direct emissions from sources owned or controlled by Santos (i.e. within Santos' operational control). For the Dorado Development, this includes a normally unmanned WHP, hydrocarbon processing on the FPSO and any transport occurring to and from these facilities that fall within Santos' operational control over a 20-year period. It also incorporates any supporting activities for the commissioning and decommissioning of facilities including those installed for future tiebacks.

Scope 2 emissions cover emissions from purchased electricity, steam, heating and cooling. Santos has identified that due to fuel gas and purchased diesel meeting on site energy requirements, there are no likely sources of Scope 2 emissions for the Dorado Development.

[1] Dorado Development is used in the remainder of the report to include oil from potential future tiebacks currently identified as prospects within the Project Area.
[2] This assumption was selected in consultation with Santos and represents a conservative approach.
[3] GHG Protocol, 'A Corporate Accounting and Reporting Standard: Revised Edition' <*https://ghgprotocol.org/sites/default/files/standards/ghg-protocol-revised.pdf*>.

Scope 3 GHG emissions are indirect emissions for the Dorado Development from assets that are not owned or controlled by Santos. In assessing the Dorado Development's Scope 3 inventory, 15 emissions categories detailed by the GHGP were reviewed for relevance and materiality. Categories included in this assessment were: purchased goods and services, capital goods, fuel and energy related activities (not included in Scope 1 or 2 emissions), business travel, downstream transport and distribution of sold product, processing of sold products, and the use of sold products. Scope 3 emissions are based on operating the Dorado Development for 20 years, with a maximum export volume of 350 MMbbl, produced from up to 38 wells from the Dorado field and future tiebacks within the Project Area.

Direct (Scope 1) GHG emissions over the lifetime of the Dorado Development[4] were calculated as approximately 15.6 $MtCO_2e$ and total indirect (Scope 3) emissions as 153 $MtCO_2e$. As illustrated in Figure ES1 below, the vast majority of Scope 1 GHG emissions occur in the operations and maintenance stage (94% of total Scope 1 emissions).

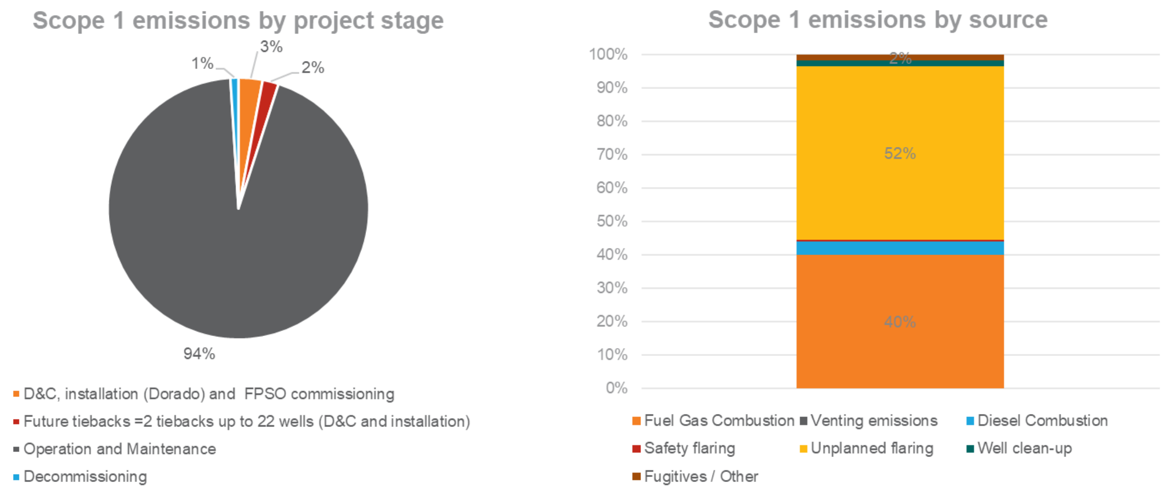

Figure ES1. Breakdown of Scope 1 GHG emissions by project stage and source

Figure ES2 shows that the final combustion of sold products makes up the majority of the Scope 3 emissions inventory (87%) followed by emissions from the refining process (9%).

[4] A 20-year period is used in our assessment.

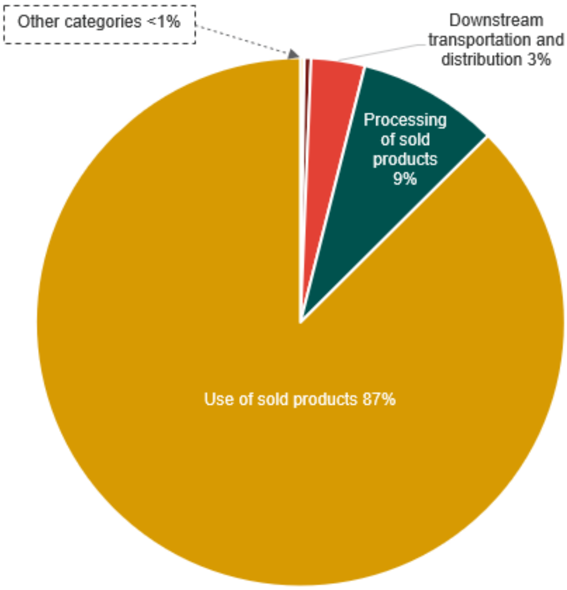

Figure ES2. Breakdown of Scope 3 GHG emissions by category

Emissions from the combustion of the sold product were conservatively estimated by assuming 100% combustion of the oil product.[5] The calculated emissions intensity for Cossack crude[6] (0.38 tCO_2e/bbl) falls within range of the average emissions intensity for oil combustion identified by the International Energy Agency (IEA).[7] However, the significance of this category to total Scope 3 emissions underscores the importance of understanding the final processing and market placement of the oil from the Dorado Development.

Other atmospheric emissions including sulphur oxides (SO_x), nitrogen oxides (NO_x), carbon monoxide (CO), volatile organic compounds (VOCs) and particulate matter (PM) were also assessed, using the National Pollutant Inventory (NPI) guidelines. Over a 20-year period, the Dorado Development will emit approximately 82,100 t of other atmospheric emissions.

Parties agree that this report may be reprinted in accordance with the purposes of the project for which it has been commissioned.

[5] This is a conservative approach as it assumes that the carbon in the oil is most rapidly released to the atmosphere as a GHG as these products are combusted in use.
[6] Used as a proxy for Dorado fluids.

List of tables

1. Introduction

Santos is planning Phase 1 of the Dorado Development in the Bedout Basin, which is offshore of north-west Western Australia and approximately 130 km north of Port Hedland. Full production is expected from 2026.[8] The Dorado Development, including oil production from the Dorado reservoir and future tiebacks (if commercially viable), currently identified as prospects, is anticipated to produce 350 million barrels (MMbbl) of oil over a 20-year life. Reservoir fluid from the Dorado Development reservoirs will be collected on a wellhead platform (WHP) and pumped by subsea infrastructure (flowlines) for processing on a floating production storage and offloading (FPSO) facility. The FPSOs headline liquids and oil processing capacity is 100,000 bopd[9] and a gas re-injection (excluding fuel gas requirements) rate of 235 MMscfd.

The Dorado Development is subject to regulatory assessment in accordance with the *Offshore Petroleum and Greenhouse Gas Storage (Environment) Regulations 2009* (Cth), administered by the National Offshore Petroleum Safety and Environmental Management Authority (NOPSEMA). Santos is required to develop an Offshore Project Proposal (OPP) detailing environmental impacts and risks arising from planned and unplanned activities associated with the project.

As an input to the OPP, Santos has requested that Energetics quantify key sources of atmospheric emissions, consistent with good industry practice and aligned with contemporary published emissions estimation methodologies. This report sets out the key findings relating to the projected emissions inventory of the proposed Dorado Development.

2. Dorado Development's emissions profile

2.1. Emissions overview

Emissions from the Dorado Development will include both greenhouse gases (GHGs) and other atmospheric emissions. GHGs are defined as gases that reradiate heat back onto the earth's surface. For our assessment, and in line with the GHG Protocol (GHGP), the quantification of GHGs included carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O). The assessment of other atmospheric emissions was based on the National Pollutant Inventory (NPI) guidelines. In addition to GHG emissions, our report also assessed sulphur oxides (SO_x), nitrogen oxides (NO_x), carbon monoxide (CO), volatile organic compounds (VOCs) and particulate matter (PM) as the most significant sources of atmospheric emissions.

The GHGP Corporate Accounting and Reporting Standard classifies a company's GHG emissions into three 'scopes'.[10] Scope 1 emissions include all direct emissions from sources owned or controlled by Santos (i.e. within Santos' operational control). Scope 2 emissions cover emissions from purchased electricity, steam, heating and cooling by Santos. Scope 3 GHG emissions are indirect emissions for the Dorado Development and are from assets not owned or controlled by Santos. These include the emissions associated with the refining and use of products from the Dorado Development. Santos has identified that due to fuel gas and purchased diesel meeting on

[8] First oil targeted in December 2025.
[9] Headline capacities expressed in units as provided by Santos to provide continuity across the project.
[10] GHG Protocol, 'A Corporate Accounting and Reporting Standard: Revised Edition' <https://ghgprotocol.org/sites/default/files/standards/ghg-protocol-revised.pdf>. https://ghgprotocol.org/sites/default/files/standards/ghg-protocol-revised.pdf

site energy requirements, there are no likely sources of Scope 2 emissions for the Dorado Development.

The following sections describe the emissions boundary applied to Phase 1 of the Dorado Development, the methodology for calculating atmospheric emissions and Scope 1 and 3 GHG emissions, and a summary of the resulting emissions inventories.

2.2. Emissions boundary

The boundary of assessment of the Dorado Development is defined by two key operational aspects:

- The operation of the FPSO for a 20-year period
- The production, processing, and sale of 350 MMbbl of oil from the Dorado reservoir and potential future tiebacks yet to be appraised.

Figure 1 presents a high-level overview of processing steps to occur on the FPSO and the downstream activities related to the processing and sale of the oil.

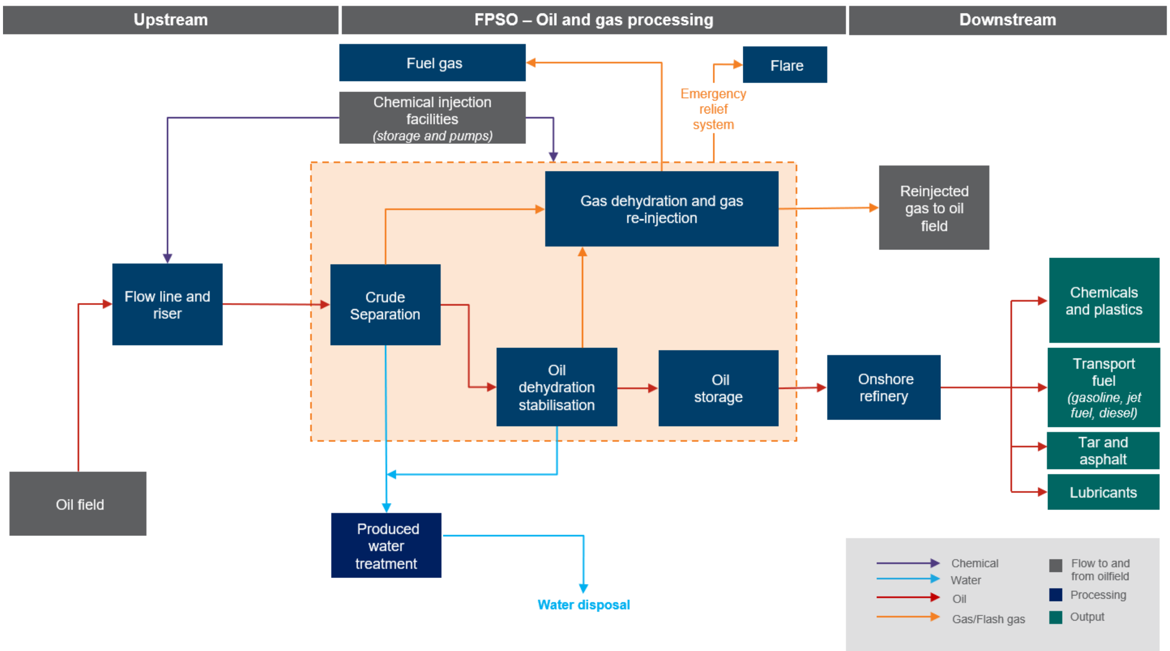

Figure 1. Flowsheet of Dorado operations highlighting Scope 1 and 3 emissions sources

In assessing atmospheric and Scope 1 GHG emissions, most parameters related to processing oil on the FPSO have been defined on the assumption that the FPSO runs at full (100%) capacity and are independent of the total oil processed. Given that the FPSO will have scheduled maintenance shutdowns, as well as the potential for emergency shutdowns or unplanned events resulting in "down time", this assumption is considered conservative. Fugitive emissions from the FPSO are dependent on the quantity of oil produced and contributes less than 1% to the Scope 1 GHG emissions profile.

Calculations of Scope 3 emissions are based on the assumption that 350 MMbbl of oil will be produced by the Dorado reservoir and future tiebacks. Any changes in the quantity of oil produced from the FPSO will result in changes in Scope 3 emissions, particularly for emissions from the transport, processing and end use of the sold product. Consequently, the boundary of our assessment includes the production, onshore processing and use of 350 MMbbl of oil from the Dorado Development with future tiebacks.

The characteristics of the oil from the Dorado field and future tiebacks targeting similar geological formations, have largely been approximated by Caley crude oil. As no estimates for the refining slate of Caley crude were readily available, we considered public sources of similar light, sweet condensates. Cossack crude was identified as the closest to these in terms of geographic location and API. Cossack crude is extracted from the North West shelf and exhibits an API of 48.8, comparable with Caley, and adopted as the proxy for this inventory assessment.

Our assessment assumes that the oil is processed onboard a FPSO operating for 20 years at full capacity and includes emissions from the commissioning and decommissioning of the WHP and FPSO. In consultation with Santos, Energetics has assumed that 100% of the Dorado Development's product will be shipped to Kobe, Japan for refining.[11] The final products from the refining process were assumed to follow the typical slate from the processing of Cossack crude. Energetics has conservatively assumed that all of the final refining products are combusted.[12] Figure 2 provides a summary of these boundaries with key assumptions described in further detail in Section 2.3.4 and 2.4.2.

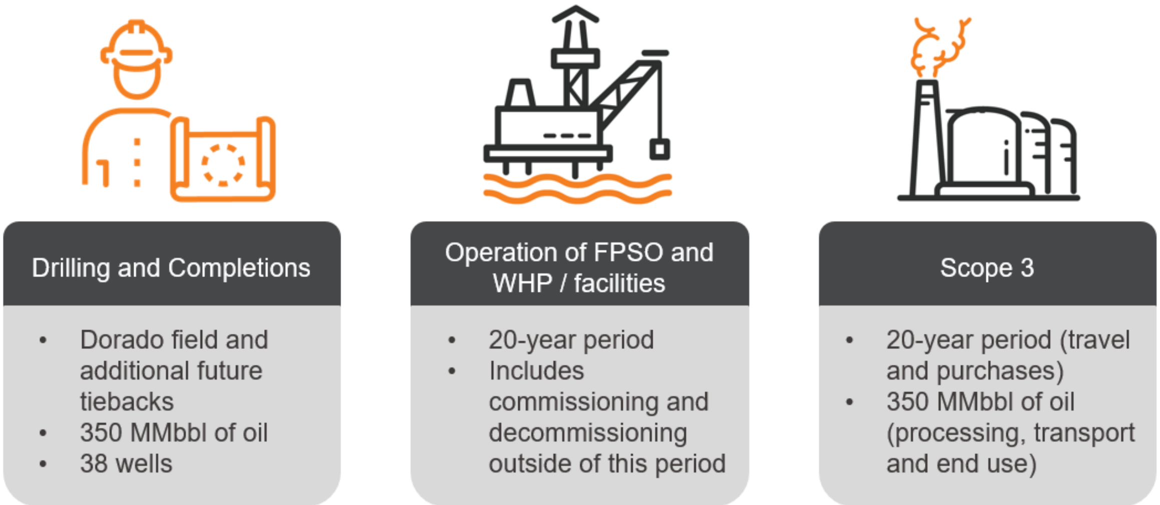

Figure 2. Defined boundaries for the Dorado Development

2.3. Direct emissions (Scope 1)

2.3.1. Calculating direct emissions

Greenhouse gas emissions

To calculate Scope 1 GHG emissions, Energetics adopted the methodology outlined in the *National Greenhouse and Energy Reporting (Measurement) Determination 2008* (Cth) (NGER Determination) together with emissions factors outlined in the federal Department of Industry,

[11] Japan was identified as one of the likely end customer countries and therefore was assumed to be the location of the port to which oil would be shipped, reflecting a conservative approach since shipping to Japan represents the farthest distance from the Dorado location that is likely to be travelled.
[12] This assumption was selected in consultation with Santos and represents a conservative approach.

Science, Energy and Resources' (DISER)[13] National Greenhouse Accounts (NGA) factors (August 2021).[14] The NGA factors draws on the NGER Determination and uses the National Greenhouse and Energy Reporting (Measurement) Amendment (2020 Update) Determination 2020.[15]

For each activity, an appropriate methodology for calculating emissions was selected from the NGER Determination. Data was converted into the appropriate units and multiplied by the required emissions factor to determine the carbon dioxide equivalent (CO_2e) amounts of CO_2, CH_4, and N_2O emissions. This allows the direct comparison of emissions sources and is aligned with global best practice in GHG accounting.

Other atmospheric emissions

To calculate other atmospheric emissions, guidance manuals developed for the NPI were used. These were primarily:

- Emission Estimation Technique (EET) Manual for Oil and Gas Extraction and Production (Version 2.0)
- EET Manual for Combustion Engines (Version 3.0)
- EET Manual for Fuel and Organic Liquid Storage (Version 3.3).

Similar to the method applied for GHG emissions, the manuals were used for both the method and emissions factors. A summary of the activities and the corresponding estimation method and emissions factor for both GHGs and other atmospheric emissions are presented in Appendix A.

2.3.2. Direct emissions boundary

Scope 1 emissions include all direct emissions from sources owned or controlled by Santos (i.e. within Santos' operational control). For the Dorado development, this includes operations occurring within the Dorado WHP and the FPSO and any transport occurring to and from these sites, that falls within Santos' operational control over a 20-year period. It also incorporates any supporting activities for the commissioning and decommissioning of the WHP and FPSO and associated activities or infrastructure installation for future tiebacks, such as additional wells, WHP or subsea facilities or pipelay.

The assessment of Scope 1 emissions covered the following stages of the Dorado Development:

- ***Drilling and completions (D&C), installation and commissioning***: includes the installation of infrastructure such as WHPs and flowlines, drilling of the production wells (including tiebacks) and commissioning of WHP and the FPSO
- ***Operations and maintenance (O&M)***: includes all activities which occur during a 20-year operation of the FPSO assuming 350 MMbbl of oil from the Dorado field and future tiebacks
- ***Decommissioning***: includes all activities related to well plugging and abandonment, and the removal of the WHPs and any supporting infrastructure.

Key assumptions for each operating stage are described in the following sections.

[15] Compiled on 1 July 2021. Current at the date of the revised version of this report (February 2022).

2.3.3. Operations breakdown and sources of emissions

In conjunction with Santos' engineers, Energetics identified the key activities which could release GHGs and/or atmospheric emissions within each project stage.

D&C, installation and commissioning

During this phase, key activities identified include the use of diesel for the mobile offshore drilling unit (MODU), support vessels servicing the MODU, diesel use for power generation and the flaring of liquid and gas produced during the unloading and clean-up of each well. Up to 38 wells have been assumed for the Dorado Development.

Operations and maintenance

Fuel gas

Fuel gas is used on the FPSO for powering generation turbines and to drive turbines associated with gas compression which may include re-injection compressors or low-pressure flash gas compressors. The fuel gas used in this equipment will be sourced from the process and originates from the reservoir. The majority of process gas is reinjected back into the reservoir as standard operational procedure. This is required to enhance and maximise the liquids recovery.

Flaring

During the operations and maintenance stage, the possible requirement for the flaring of gas can be separated into safety and unplanned flaring events associated with non-routine events:

- Safety flaring accounts for the pilot flame
- Unplanned flaring occurs during process trips which could be triggered by unforeseen events, including intermittent blanket gas flaring and maintenance activities. This accounts for unplanned flaring which also includes blowdown events, pressure relief events, process upsets which lead to flaring, flaring due to equipment down time and flaring for maintenance purposes.

Unplanned flaring activities may occur and further emissions reduction methods may also be defined and applied during Front End Engineering Design (FEED) and detailed engineering design yet to commence. For example, off gas from flaring may be sent to the vapour recovery system and reinjected into the reservoir. However, to apply a conservative approach, the emissions assessment has been based on the upper bound of safety and unplanned flaring to occur in the 20 year period (36.5 MMscfd of safety and 3,750 MMscf per year of unplanned flaring) inclusive of all potential flaring sources.

Diesel combustion

During this stage, diesel combustion will be limited to diesel used for power generation when the FPSO is not on station (assumed as approximately 15 days of the year) and diesel use associated with testing equipment such as the fire pump. While there may be other sources of miscellaneous diesel use on the FPSO and WHP (i.e. use by the lifeboat, emergency generators and fast rescue craft) this was deemed to be negligible relative to the aforementioned sources.[16] This is a fair assumption based on our understanding of similar inventories and the magnitude of these emissions sources. Diesel use in support vessels and helicopters for the transport of personnel to

[16] It was noted that the FPSO may utilise additional diesel in the case that the FPSO is required to sail away due to a cyclone or other adverse weather conditions. However, as the frequency and sail away distances in such events can be difficult to predict and is expected to have a marginal impact, this is excluded from the emissions inventory.

and from the WHP/FPSO is excluded from Scope 1 GHG emissions as these activities are operated by a third party; they are therefore included in the Scope 3 GHG assessment (see Section 2.4).

Fugitive emissions

Fugitive emissions occur as a result of minor leaks from equipment. Sources of fugitive emissions from the Dorado Development include emissions during the transfer of gas and oil through equipment, the storage of diesel and oil in the FPSO and the offloading of oil. To minimise these emissions during production and offloading operations, the Dorado Development will include a vapour recovery system which supplies a blanket gas for all cargo and slops tank. A blanket gas fills the vapour space of the tanks preventing the formation of an explosive vapour-air mixture. However, to adopt a conservative approach in estimating emissions, Energetics has included unmitigated fugitive emissions from storage tanks in the emissions inventory.

Decommissioning

During the decommissioning stage, emissions will primarily result from the combustion of diesel in the MODU, generators and support vessels. Based on Santos' prior experience, the activities in this stage are likely to be similar to those in the drilling stage (with the exception of flaring as well clean-up is not anticipated). To estimate emissions from this stage, daily diesel usage from drilling has been applied to the time frame of the decommissioning stage (152 weeks based on 38 wells and four weeks to decommission each well). Table 1 summarises the activities in each project stage.

Table 1. Activities resulting in Scope 1 emissions from the Dorado Development

Activities	D&C, installation and commissioning	Operations and maintenance	Decommissioning
Fuel gas combustion for compressors and electricity generation		✓	
Flaring (well clean-up and FPSO commissioning)	✓	✓	
Fugitive emissions –oil and gas throughput		✓	
Fugitive emissions –oil and diesel storage		✓	
Diesel combustion – gensets	✓	✓	
Diesel combustion – support vessels and jack up MODU*	✓		✓
Produced water		✓	
Acetylene combustion		✓	

Activities	D&C, installation and commissioning	Operations and maintenance	Decommissioning
Lubricant oils		✓	
Oil loading		✓	

** the use of support vessels in other stages will be third party operated and are quantified as Scope 3 GHG emissions*

2.3.4. Key assumptions

Key assumptions regarding start dates, duration and activities for each operating stage are listed in Table 2. These assumptions are based on information provided by Santos in response to Energetics' requests. Assumptions were based on the best data available at the time of the assessment. Where data or activities are yet to be defined, Santos' assumptions have been derived from data from similar operations or prior experience.

Table 2. Key assumptions applied in developing the Scope 1 emissions inventory

Stage	Activity	Assumption
General	Oil production	350 MMbbl of oil produced in the 20-year period.
	Oil composition	Crude condensate assay results indicate the Dorado well will produce a mixed condensate product from multiple reservoir members (Archer Formation). Caley PS-E (51.4° API, 189 ppm wt sulphur) will form the majority of the condensate (80%) followed Baxter condensate (51.0° API, 133 ppm wt sulphur) (20%). Assay results representing the BoD analysis of the condensate from these two sources were used to estimate the speciation of VOC components which would be released upon the flaring of condensate (in the drilling stage) and related in the form of fugitive emissions during the loading/offloading of condensate (O&M).
	Oil properties	Specific gravity of condensate is 0.779.
	D&C, commissioning and decommissioning	No use of acetylene and lubricant oils in the drilling & completions, commissioning, and decommissioning stage.
	General	Heat rate of Solar Titan[17] = 10,160 kJ/kWhr Heat rate of Solar Taurus = 11,265 kJ/kWhr LHV of gas = 46.3 GJ/tonne LHV of diesel = 43 GJ/tonne Gas – specific gravity = 0.82 Gas density = 1.0 kg/m^3 Annual run hours = 8,760 hours (based on operating 365 days at 24 hours per day) Diesel energy content = 38.6 GJ/kL[18] Specific gravity of diesel = 0.84 Density of lubricant oil = 950 kg/m^3[19]

[17] Assumed industry standard compressors given concept engineering phase of the Dorado Development (as provided by Santos).
[18] NGER Determination.
[19] ***https://www.neste.com/companies/products/lubricants/basic-consepts-lubricants***

Stage	Activity	Assumption
D&C, installation and commissioning	**Start date**	**Drilling (Dorado):** 1 January 2024[20] **Drilling (Dorado infill wells):** approx. year 6 of O&M **Drilling (future tieback 1):** approx. year 6 of O&M **Drilling (future tieback 2):** approx. year 10 of O&M **Commissioning:** 1 October 2025
	Duration	**Drilling (Dorado and future tiebacks):** duration of drilling and completions is 1.75 years for Dorado, future tieback 1 and future tieback 2 **Installation:** 4 months prior to the commencement of drilling activities of each field **Drilling (Dorado infill wells):** Four infill wells to be drilled in year 6 of O&M for the Dorado field only, which is assumed to take a period of 140 days **Commissioning:** 3 months following the completion of drilling the Dorado wells and before full production
	Drilling activities	Primary drilling activities consist of diesel use for support vessels and flaring. All other activities likely to be immaterial.
	Diesel use	Primary diesel use during drilling activities is for support vessels. Each support vessel is assumed to use 12m^3 of diesel per day. All other activities likely to be immaterial. Key assumptions for each stage: **Drilling and completions**: • **Dorado (16 wells) and infill wells (4 wells)**: 3 support vessels per day for the duration of the drilling period of Dorado and infill wells (1 support vessel assumed to only operate for 6 months of the drilling period) • **Future tieback 1 (12 wells) and future tieback 2 (10 wells)**: 3 support vessels per day for the duration of the drilling period, with 1 support vessel assumed to only operate for 6 months of the drilling period. The volume of fuel use per vessel per day has been scaled according to the number of wells that need to be drilled relative to the Dorado field (e.g, with 12 wells at future tieback 1, support vessels are assumed to only be required 75% of

[20] Start date of the MODU assumed to be 1st January 2024, with the installation activities for the WHP occurring in Q4 2023. The dates for the purpose of this assessment are nominal, with durations assumed based on historical project activity experience and historical drilling activities undertaken in the Bedout Basin.

Stage	Activity	Assumption
		the time relative to the Dorado field which has 16 wells). **Installation (Dorado and future tiebacks)**: 5 support vessels required per day for the duration for 4 months for each field. **Commissioning**: 5 support vessels required per day for the duration of 4 months.[21]
	Flaring	**Drilling and installation**: Includes well clean-up for wells drilled for the Dorado Development (including tiebacks) over the 2-year period. Clean up occurs periodically over the 2-year period of drilling activities. • **Gas flaring volumes**: 25,000t (Dorado and infill wells: 10,542 t, future tiebacks: 14,470 t) • **Hydrocarbon flaring:** 54,247t (Dorado and infill wells: 27,331 t, future tiebacks: 26,916 t) **Commissioning:** Includes any excess gas flared during commissioning. To account for this, the flare (based on concept design) is assumed to operate at its peak design rate for a period of 72 hours (assumed to flare 21,434 tonnes) as advised by Santos. Flare destruction of all gas flaring activities at 98-99% of total VOCs.
Operations and maintenance	**Start date**	**Full production assumed at 1 January 2026**
	Duration	20 years
	Safety flaring	0.1MMScfd, accounts for the pilot flame
	Unplanned flaring	3,750 MMscf per year assuming 15 extended flaring events at 48 hours per event and half flare rates. Given the Dorado Development is still in concept engineering, this assumption is highly conservative and will be more defined during FEED and detailed engineering. The assumption assumes one "unplanned" flaring event per month, along with up to three shutdowns for cyclone avoidance per year. These unplanned events may be associated with process upsets, gas

[21] Conservative estimate as commissioning is assumed to take 3 to 4 months, only one commissioning period associated with the FSPO itself.

Stage	Activity	Assumption
		compressor downtime and cyclone avoidance. The basis of the volume is estimated as a worst case at half of the potential reservoir gas (i.e. production has been ramped down) and a period of 48 hours to allow for repairs.
	Gas reinjection	Annual gas reinjection assumed constant through the 20 years period independent of crude production (235 MMscfd).
	Compressors	The maximum power of the compressors has been used for all calculations with the assumption that the FPSO operates at 100% capacity for 20 years Equipment: • Reinjection compressors – Solar Titan 130 (11.7 MW, 15.7 MW maximum power) • HP (Flash Gas compressor) – Solar Taurus 60 (5.75 MW)
	Diesel use	Includes diesel use in gensets, fire water pumps and diesel used for testing. All other activities likely to be immaterial. Diesel engine efficiency assumed to be 26%.
	Fugitive emissions	While there is a vapour recovery system in place to reduce emissions from crude tanks, to be conservative all fugitive emissions are accounted for in this inventory and are based on the total throughput of gas through the facility.[22]
	Venting emissions	Any vented emissions will be captured via the vapour recovery system. There are no emissions expected to be vented during operation.
	Fuel gas	Fuel gas composition applied to all fuel gas compressor activities, generator activities and flaring activities. Ethane is excluded from the VOCs calculation. While not specifically excluded under the NPI definition of VOCs[23] it has minimal photochemical activity so would likely be excluded. For comparison, it is excluded from the US definition of VOCs.[24]

[22] Throughput has been assumed to be the total volume of gas extracted from the wells (i.e. the sum of the volume of gas reinjected, flared, and used as fuel gas).
[23] http://www.npi.gov.au/resource/npi-definition-volatile-organic-compounds

Stage	Activity	Assumption
	Produced water	Table 7-13 of OPP states maximum design rate for produced water is 4,350 m^3/day; this is the value used in the calculations; tCO_2-e/ML, is equivalent to $kgCO_2$-e/m^3.
	Tank cleaning	While the crude oil tanks are planned to be cleaned every five years, given the nature of the hydrocarbon, i.e., a light condensate, Santos does not expect be measurable additional emissions associated with the tank cleaning process for the five-yearly inspections. This is because it is unlikely that much residue/sludge would accumulate in the tank bottoms.
Decommissioning	**Start date**	**1 January 2046**. For the purpose of inventory assessment, it is assumed that decommissioning commences at end of 20-year operations life.
	Duration	Approximately 3 years (4 weeks per well for plug and abandonment activities, approximately 38 wells including future tie backs).
	General	Activities in the decommissioning stage are estimated to be the same as the drilling stage (diesel use for the MODU and support vessels only) but adjusted for a 3-year period. This assumption is based on prior experience by the team. No flaring expected in this stage.

[24] https://www.epa.gov/air-emissions-inventories/what-definition-voc

A summary of the volume of gas released, combusted, and reinjected by the facility is summarised in Table 3.

Table 3. Breakdown of total gas flows according to project activity[25]

Stage	Activity	Location	Unprocessed gas (tonnes)	Contribution to total gas flows in project lifetime[26]
Drilling and installation	Flaring	Dorado wells (12)	10,500	0.0195%
Drilling and installation	Flaring	Dorado infill wells (4)	0.00189	<1%
Drilling and installation	Flaring	Tie backs (up to 22)	14,500	0.0269%
Commissioning	Flaring	FPSO	21,400	0.0398%
O&M	Safety flaring	FPSO	20,900	0.0387%
O&M	Unplanned flaring	FPSO	2,140,000	3.98%
O&M	Compressor fuel gas	FPSO	2,600,000	4.83%
O&M	Gas reinjected	FPSO	49,100,000	91.1%
O&M	Gas vented	FPSO	0	0.00%
O&M	Fugitives	FPSO	3,650	0.00678%

The assumed oil production timeline for the purpose of this inventory assessment is illustrated in Figure 3. Drilling for future tiebacks may take place following the first year of full production from the primary Dorado field. All D&C, installation and commissioning activities related to future tiebacks are assumed to be completed by 2035 for this assessment. Based on the oil production profile including the future tiebacks, the year of maximum production is anticipated in 2030. All wells are assumed to commence being decommissioned from 2046 onwards.

[25] To 3 significant figures
[26] Includes D&C and installation

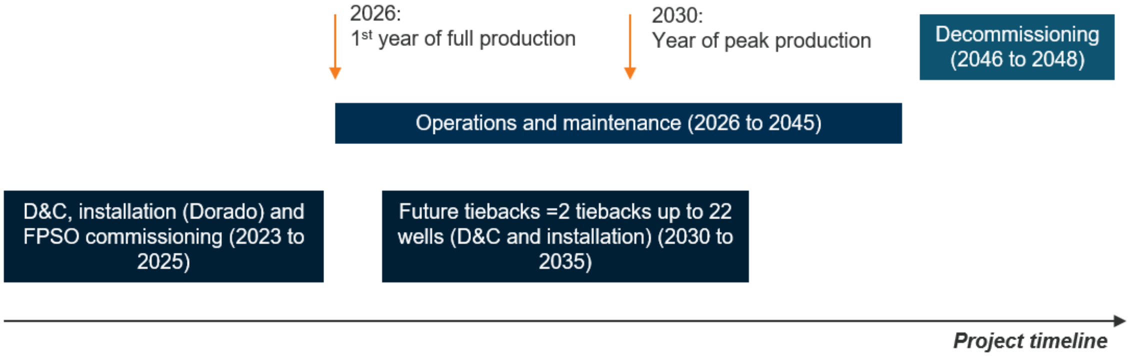

Figure 3. Assumed oil production schedule (for the purpose of this inventory assessment) from Dorado field and future tiebacks

2.3.5. Scope 1 GHG inventory

Scope 1 GHG emissions from the Dorado Development were calculated to be approximately 15.6 $MtCO_2e$. This is equivalent to 732 $ktCO_2e$ per year based on total emissions over the 20-year period and 767 $ktCO_2e$ per year based on the year of highest production.[27] Of Scope 1 emissions, 85% is CO_2 followed by 15% CH_4 with minimal N_2O. A detailed breakdown of direct GHG emissions and sources is presented in Appendix B.

The emissions breakdown by project stage and emissions source is included in Figure 4. The majority of emissions occur in the O&M stage (94% of total emissions), with flaring activities contributing to 53% of total lifetime emissions. This is followed by the combustion of fuel gas (40% of total emissions). It should be reiterated that fugitive emissions calculated in this inventory have likely been overestimated and are expected to be minimised by the vapour recovery unit in place on the FPSO.

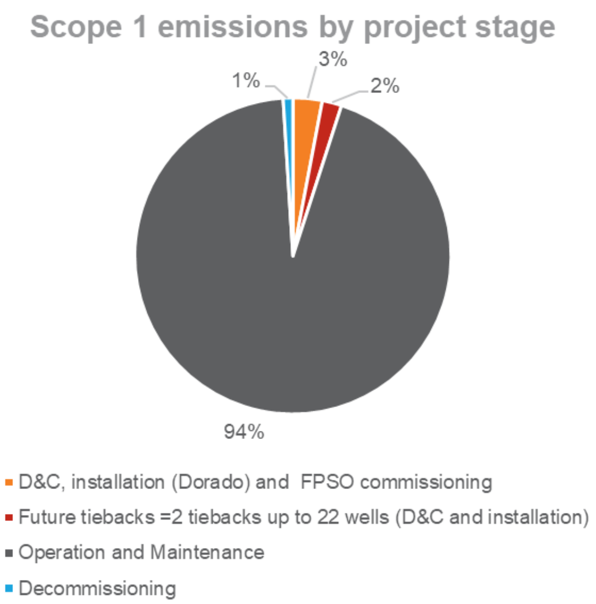

Figure 4. Scope 1 emissions breakdown by project stage

[27] Annualised emissions apply only to the O&M stage and exclude D&C, installation and commissioning.

2.3.6. Atmospheric emissions

Key atmospheric emissions identified include NO_x (45% of other atmospheric emissions), followed by CO (35% of other atmospheric emissions) and VOCs (19%) (see Figure 5). Emissions of SO_x and PMs, while present, are less than 1% of key atmospheric emissions. Due to the high volume of flaring in the O&M stage relative to other stages, this phase is the most significant contributor of atmospheric emissions during the project.

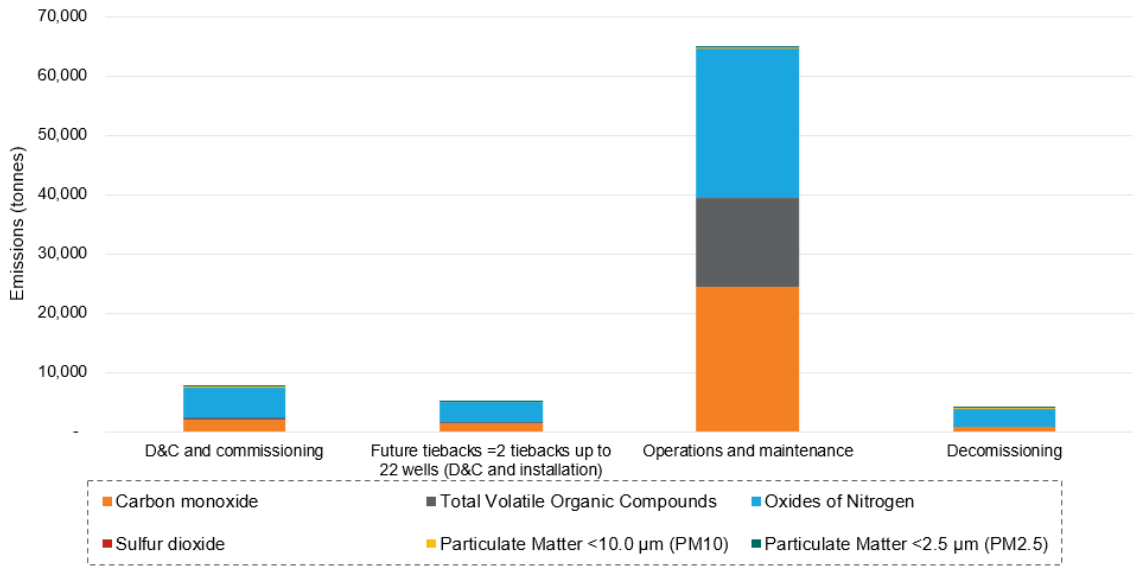

Figure 5. Other atmospheric emissions from the Dorado Development

2.4. Indirect emissions (Scope 3)

2.4.1. Scope 3 boundary

In assessing the Dorado Development's Scope 3 inventory, Energetics used the guidance provided in the GHGP Corporate Value Chain (Scope 3) Accounting and Reporting Standard[28] to identify, categorise and quantify value chain emissions. Together with Santos, the 15 emissions categories detailed by the GHGP were reviewed for relevance and materiality to the Dorado Development's value chain. Table 4 provides a summary of these categories together with explanations for their inclusion or exclusion from the Scope 3 inventory.

[28] Greenhouse Gas Protocol, 'Corporate Value Chain (Scope 3) Accounting and Reporting Standard' < ***https://ghgprotocol.org/sites/default/files/standards/Corporate-Value-Chain-Accounting-Reporing-Standard_041613_2.pdf***>.

Table 4. Scope 3 emissions categories and their relevance to the Dorado Development

GHGP Category	Description	Inclusion	Relevance to the Dorado Development's emissions boundary
1. Purchased goods and services	Extraction, production, and transportation of goods and services purchased or acquired by the reporting company in the reporting year, not otherwise included in GHGP Categories 2 to 8	✓	• Limited to chemicals purchased for the Dorado processing facility including the flowlines, risers, WHP, and FPSO and infrastructure for future tiebacks • The purchase of fuel is included in GHGP category 3 • At this stage of the project development, there is limited information available on any other goods and services
2. Capital goods	Extraction, production, and transportation of capital goods purchased or acquired by the reporting company in the reporting year	✓	• Limited to Dorado processing facility including the risers, WHP, and FPSO and infrastructure for future tiebacks • The mass of the steel which makes up the structure of the WHP and FPSO were used to quantify this category
3. Fuel- and energy-related activities (not included in Scope 1 or Scope 2)	Extraction, production, and transportation of fuels and energy purchased or acquired by the reporting company in the reporting year, not already accounted for in Scope 1 or Scope 2	✓	• Limited to Dorado processing facility including the risers, WHP and FPSO and infrastructure for future tiebacks • Fuel sources identified in Scope 1 emissions inventory were used to quantify this category
4. Upstream transportation and distribution	Transportation and distribution of products purchased by the reporting company in the reporting year between a company's tier 1 suppliers and its own operations (in vehicles and facilities not owned or controlled by the reporting company)	×	This category will be excluded as: • The development forms part of the upstream sector of oil and gas value chain • The transportation and distribution of goods upstream is likely to be immaterial noting that the transport of raw materials like diesel to the FPSO will be covered in GHGP category 3 (fuel and energy related activities) and Scope 1 transport related emissions. • Other related emissions to upstream transport (i.e. transport of diesel from supplier to barge) are outside the scope of Santos' sphere of influence The exclusion of this category is in accordance with the size and influence criteria Table 6.1 of the Protocol

GHGP Category	Description	Inclusion	Relevance to the Dorado Development's emissions boundary
5. Waste generated in operations	Disposal and treatment of waste generated in the reporting company's operations in the reporting year (in facilities not owned or controlled by the reporting company)	×	This category is excluded on the basis that: • Water waste is proposed to be overboarded, and no solid waste is produced • There is a lack of standardised emissions factor for this waste source together with limited data availability on the organic content of the liquid waste • The emissions source is unlikely to be material relative to the whole Scope 3 inventory
6. Business travel	Transportation of employees for business-related activities during the reporting year (in vehicles not owned or operated by the reporting company)	✓	• Limited to travel associated with the workforce during project preparation, installation activities and travel of workforce to and from site during the operations and maintenance phase of the project • Specifically includes flights of team from head office (Perth) to Dampier and transport from Dampier to FPSO (via helicopter and support vessels)
7. Employee commuting	Transportation of employees between their homes and their worksites during the reporting year (in vehicles not owned or operated by the reporting company)	×	This category will be excluded from the emissions inventory on the basis that material emissions associated with the movement of people are included in Category 6
8. Upstream leased assets	Operation of assets leased by the reporting company (lessee) in the reporting year and not included in Scope 1 and Scope 2 – reported by lessee	×	This category will be excluded due to: • Lack of clarity at this stage of development on the potential use of leased assets, based on project concept, and not yet in FEED and detailed design phase • The emissions source is unlikely to be material relative to the whole inventory

GHGP Category	Description	Inclusion	Relevance to the Dorado Development's emissions boundary
9. Downstream transportation and distribution	Transportation and distribution of products sold by the reporting company in the reporting year between the reporting company's operations and the end consumer (if not paid for by the reporting company), including retail and storage (in vehicles and facilities not owned or controlled by the reporting company)	✓	Limited to transport from the FPSO to the facility at which crude will be processed
10. Processing of sold products	Processing of intermediate products sold in the reporting year by downstream companies (e.g., manufacturers)	✓	Limited to the processing that occurs to produce the immediate outputs from the oil refinery
11. Use of sold products	End use of goods and services sold by the reporting company in the reporting year	✓	Limited to the combustion of fuels as a conservative assumption
12. End-of-life treatment of sold products	Waste disposal and treatment of products sold by the reporting company (in the reporting year) at the end of their life	×	Excluded as this category is limited to the combustion of fuels and excludes any downstream emissions related to the production and use of plastics and chemicals. The combustion of fuels is covered in GHG category 11 - Use of sold products
13. Downstream leased assets	Operation of assets owned by the reporting company (lessor) and leased to other entities in the reporting year, not included in Scope 1 and Scope 2 – reported by lessor	×	Excluded as downstream leased assets will fall under the company-wide emissions reporting and are not specific and/or significant to the Dorado Development
14. Franchises	Operation of franchises in the reporting year, not included in Scope 1 and Scope 2 – reported by franchisor	×	Excluded as downstream leased assets will fall under the company-wide emissions reporting and are not specific and/or significant to the Dorado Development

GHGP Category	Description	Inclusion	Relevance to the Dorado Development's emissions boundary
15. Investments	Operation of investments (including equity and debt investments and project finance) in the reporting year, not included in Scope 1 or Scope 2	×	Excluded as downstream leased assets will fall under the companywide emissions reporting and are not specific and/or significant to the Dorado Development

2.4.2. Key assumptions

The Protocol categories 1, 2, 3, 6, 9, 10 and 11 were identified as relevant to the Dorado Development's Scope 3 inventory. However, as the Dorado Development is at an early stage of development, there is limited information on where the oil will be sold, how it will be processed and who the end user will be. As such, Energetics has applied a series of assumptions, aiming to maintain a conservative approach in estimating emissions. These key assumptions are detailed below.

Category 1, 2, 3 and 6: Purchased goods and services, capital goods, fuel use and business travel

Table 5 summarises the key assumptions for Category 1, 2, 3 and 6.

Table 5. Assumptions used in the calculation of emissions from Category 1, 2, 3 and 6

Category	Assumptions
Category 1: Purchased goods and services	• Purchased goods limited to chemical use • Chemicals purchased based on use during the 20-year operational period[29] • While other purchased goods are not included, primarily due to a lack of data, other emissions from purchased goods are likely to be immaterial
Category 2: Capital goods	• Includes the mass of major capital goods (FPSO, WHP and future tieback infrastructure) only • Assumes the WHP, FPSO and materials required for drilling/ wells are primarily steel. To account for any other materials and construction of the capital goods, an uplift factor of 30% is applied to the emissions factor • Assumes the installation of 3 WHPs (allowance for WHPs to support future tiebacks) • Excludes any equipment on the FPSO and the any equipment related to the risers

[29] Underlying operational assumptions defined by Santos.

Category	Assumptions
Category 3: Fuel- and energy related activities (not included in scope 1 or scope 2)	• Diesel purchased is the only fuel included in this category. Other fuel used for the FPSO is supplied from fuel gas from the reservoirs.
Category 6: Business travel	• Assumes travel via helicopters (three flights per week) and support vessels (one per week) occurs from Dampier to Dorado field for the operational period of 20 years • Assumes flights from Perth to Dampier for personnel (five flights per week)

Category 9: Downstream transportation and distribution

Energetics has assumed that 100% of the Dorado Development's product will be shipped to Kobe, Japan for refining (this is the furthest potential port that the Dorado crude is likely to be shipped to). To maintain a conservative approach, we have also assumed that the return trip of the cargo ship from the final destination port to the loading port is included in this category (the ship returns empty).

Category 10: Processing of sold products

Santos has indicated that the oil produced from the Dorado Development (Dorado reservoir and potential future tiebacks) can be approximated to Caley crude oil. Crude condensate assay results indicate the Dorado well will produce a mixed condensate product from multiple reservoir members. Caley PS-E (51.4° API, 189 ppm wt sulphur) will form the majority of the condensate (80%) followed Baxter condensate (51.0° API, 133 ppm wt sulphur) (20%). As no estimates for the refining slate of Caley or Baxter crude were readily available to be used in this assessment, we considered public sources of similar light, sweet condensates. Cossack crude was identified as the closest to these in terms of geographic location and API and adopted as the proxy for the purpose of this assessment. Cossack crude is extracted from the North West shelf and exhibits an API of 48.8, comparable with Caley and Baxter.

Category 11: Use of sold products

The distillation yields of Cossack crude are shown in Table 6. Following a conservative approach, 100% of the oil product was assumed to be combusted. While Energetics recognises that vacuum residues are commonly used to produce non-fuel products, we have applied a conservative assumption that this fraction is combusted using the emissions factor for fuel oil based on the categorisation of this heavy residue product as low sulfur waxy residue.

Table 6. Typical yield output from the distillation of Cossack crude[30]

Substance	Yield through distillation (%)
LPG	3%
Light naphtha	36%
Heavy naphtha	0%
Kerosene	21%
Diesel	0%
Gasoline	26%
Light vacuum gas oil	13%
Heavy vacuum gas oil	0%
Vacuum residue	2%

2.4.3. Method

Wherever possible, emissions factors were sourced from the DISER's compilation of NGA factors. This specifically applied to Category 11, where the emissions related to the combustion of fuel products were sourced from Table 3 of the DISER's NGA factors, the regulated data set for this type of calculation should emissions occur as Scope 1 emissions. For the calculation of emissions related to Category 1, the Ecoinvent Database (v3) was used as the source of life cycle emissions factors.[31] Ecoinvent v3 is the most recent iteration of the globally used Ecoinvent life cycle inventory (LCI) database. While an Australian implementation of the Ecoinvent database, AusLCI (based on Ecoinvent v2.2) is available, this version does not contain all the required LCI data. For consistency, we have used Ecoinvent v3 throughout. Detailed assumptions used to calculate emissions are outlined in Appendix A.

2.4.4. Scope 3 GHG inventory

Scope 3 GHG emissions from the Dorado Development (on the basis of the initial Dorado field, and future tiebacks yielding 350 MMbbl) were calculated to be approximately 153 $MtCO_2e$. This is equivalent to 7.59 $MtCO_2e$ per year based on total emissions over the 20-year period and 20 $MtCO_2e$ per year based on the year of highest production.[32]

The summary of GHG emissions from activities in the Dorado Development's value chain is provided in Figure 6. Total Scope 3 emissions were 153 $MtCO_2e$ with the final combustion of sold products making up the majority of the Scope 3 emissions inventory (87%), followed by emissions from the refining process (9%). Downstream distribution is just over 3% of the inventory with the remaining categories making up less than 1% of emissions.

[30] BP Crude assays - Cossack Crude, ***https://www.bp.com/en/global/bp-global-energy-trading/features-and-updates/technical-downloads/crudes-assays.html***.
[31] Gregor Wernet et al, 'The Ecoinvent Database Version 3 (Part I): Overview and Methodology' (2016) 21 *International Journal of Life Cycle Assessment* 1218-30.
[32] Based on GHGP categories 9, 10 and 11.

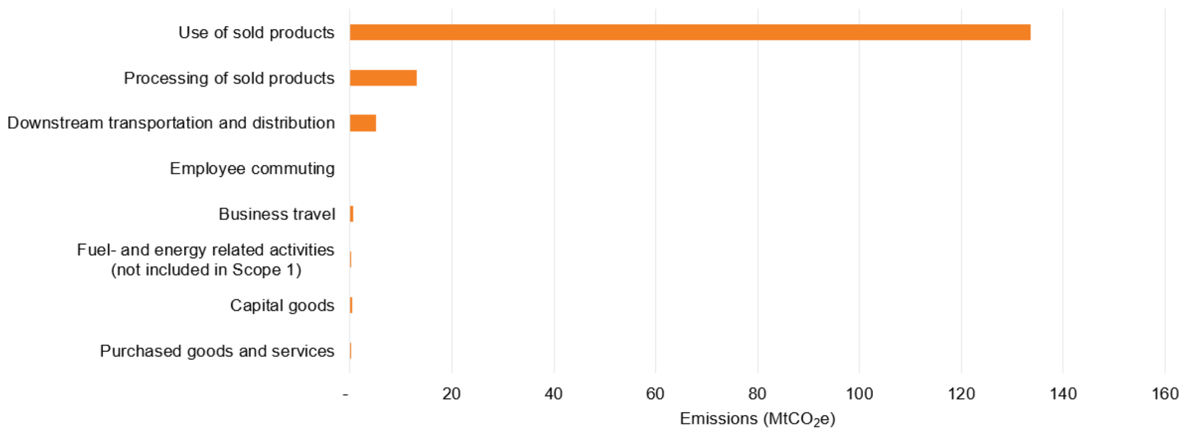

Figure 6. Scope 3 emissions in the project's value chain

2.5. Benchmarking Dorado Development's emissions

2.5.1. Benchmarking against global estimates

The total GHG emissions produced during the 20-year operation of the Dorado Development were found to be approximately 168.6 $MtCO_2e$ with direct emissions (Scope 1) and indirect emissions (Scope 3) contributing to 9% and 91% of total emissions respectively.

The product life cycle emissions were assigned to the following life cycle phases and normalised on a per barrel basis[33] as shown in Table 7 and benchmarked against global averages in Table 8.

Table 7. Emissions intensity of each stage of the Dorado Development's value chain

Phase	Categories included	Total emissions ($MtCO_2e$)	Emissions per barrel (tCO_2e/bbl)
Oil production	Scope 1 emissions Scope 3 emissions: GHGP categories 1, 2, 3 and 6	15.6	0.045
Oil transport	Scope 3 emissions: GHGP Category 9	5	0.0143
Refining	Scope 3 emissions: GHGP Category 10	13	0.0376
Final combustion	Scope 3 emissions: GHGP Category 11	134	0.382
Total		**168.6**	**0.48**

[33] Based on a lifetime production of approximately 350 Mbbl.

Table 8. Benchmarking the Dorado Development against global averages

Phase	Dorado Development (tCO_2e/bbl)	IEA Benchmark (tCO_2e/bbl)[34]
Combustion of sold products	0.38	0.41
Oil development lifecycle (flaring, transport, extraction, refining and methane emissions)	0.098	0.05-0.25

Table 8 indicates that the emissions intensity associated with the combustion of sold products from the Dorado Development is within range of the average emissions intensity identified by the International Energy Agency (IEA)[35] for oil combustion. Differences in the final intensity are likely to be driven by the assumed product slate from the refining process that is sold to end users. The end use of the oil will be driven by demand for combustible fuels. This will be influenced by technology, policy and market conditions which could shift in the lifetime of the Dorado Development. The emissions intensity for the development lifecycle activities projected for the Dorado Development are within the benchmark range.

It should be noted that as the engineering design of the Dorado Development matures, the accuracy of the emissions estimates will improve. Any significant changes to the engineering design or production profile from the assumptions presented in this report will require the emissions profile to be reviewed.

3. Conclusions

Over a 20-year period, the Dorado Development is projected to produce 350 MMbbl of oil from the Dorado field and future tiebacks. Although the final placement of the product is still under consideration, it is anticipated that Asia will be an important market for the oil.

Emissions from the Dorado Development will include GHGs and other atmospheric emissions. Over a 20-year period, the Dorado Development will emit approximately 82,100 t of other atmospheric emissions. Scope 1 GHG emissions were calculated as approximately 15.6 $MtCO_2e$ and Scope 3 emissions as 153 $MtCO_2e$. The majority of Scope 1 emissions occur in the O&M stage (94% of total Scope 1 emissions). The final combustion of sold products makes up the majority of the Scope 3 emissions inventory (87%) followed by emissions from the refining process (9%).

Based on high-level benchmarking, GHG emissions intensities from flaring at the Dorado Development and the use of the sold product are within anticipated industry ranges. However, limited publicly available data on Scope 3 emissions from oil developments makes it challenging to provide a benchmark for the overall GHG emissions intensity. We have based our assessment on best available data at the time and this may be refined as the development progresses.

About Energetics

Working with ASX200 and all levels of government, Energetics is a specialist energy and climate change risk management consultancy.

We're more than carbon neutral.

Sustainability is core to Energetics' business.

In June 2008, Energetics became one of Australia's first consulting firms to achieve carbon neutrality through the Australian Government's Greenhouse Friendly Program.

Our carbon neutrality has been certified under the Climate Active Carbon Neutral Standard (formerly the National Carbon Offset Standard – NCOS) for Organisations. Climate Active is a partnership between the Australian Government and Australian businesses to drive voluntary climate action. www.climateactive.org.au

Attachment 13 Dorado Development – Public Comment Report

#	Name/Organisation	Key Summarised comments on the OPP, including any objections or claims	Santos Assessment of Merit of comment; and response to comment	Changes made to the OPP in response to the comment[65]
1.0		They key issues are summarised below according to the submission.	Subsections of the submission are addressed below	Subsection of the submission are addressed below.
1.1	Commentor # 1	Consideration from the DISER as to why a project such as this is even being tabled.	DISER is responsible for management of offshore acreage for petroleum exploration and production. DISER releases acreage annually, following a stakeholder consultation process, for companies to bid for exploration permits (Offshore petroleum exploration acreage release process). Queries related to DISER's decision to release acreage for the Bedout sub-basin, which has subsequently resulted in the Dorado development proposal by Santos, should be directed to DISER.	Santos considers that no modification to the document is necessary.
1.2		There is a medium risk of accidental release of hydrocarbons and chemical spills. Why is a medium risk considered ok for this project.	The object of the *OPGGS (Environment) Regulations* is to ensure that petroleum activities in Commonwealth waters are carried out in a manner: + consistent with the principles of Ecologically Sustainable Development set out in section 3A of the EPBC Act; + by which the environmental impacts and risks of the activity will be reduced to as low as reasonably practicable (ALARP); and + by which the environmental impacts and risks of the activity will be at an acceptable level. For the Dorado Development, while an unplanned release event is unlikely, the potential environmental risks and impacts of a credible spill event need to be assessed and mitigated to acceptable levels. When considering environmental risk and impact from unplanned spill events, Santos considers the Environment that May Be Affected (EMBA) for each credible spill scenario (see OPP Section 7.3.1). Acceptable levels of environmental risk and impact are demonstrated through the application of control measures to mitigate environmental impacts (see OPP Section 7.1.4) and assessment against acceptability criteria (see OPP Section 7.3.1.4). Santos have reviewed and further detailed the consequence rankings for each of the environmental receptors and sensitivities impacted from an Accidental Release of Hydrocarbon or Chemical Spill. In re-evaluating the risk per receptor, the most sensitive receptors were Marine Mammals, Protected Areas and Heritage, bringing the overall consequence to Major (IV). Through this process the consequence ranking for this risk has been revised from Severe (V) to Major (IV) leading to a reduction in residual risk from Medium to Low. In accordance with the OPGGS (Environment) regulations, Santos considers the likelihood of large hydrocarbon releases and the reduction in impacts should one occur from Dorado Phase 1 to be acceptable.	A consequence ranking was applied to each environmental sensitivity for the Accidental Release – Hydrocarbon and Chemical Spill sections, including: + **Section 7.3.1.2.1** – Water Quality + **Section 7.3.1.2.2** – Sediment Quality + **Section 7.3.1.2.3** – Air Quality + **Section 7.3.1.2.4** – Benthic Habitats + **Section 7.3.1.2.5** – Coastal Habitats + **Section 7.3.1.2.7** – Key Ecological Features + **Section 7.3.1.2.8** – Marine Mammals + **Section 7.3.1.2.10** – Birds + **Section 7.3.1.2.11** – Fish + **Section 7.3.1.2.12** – Protected Areas + **Section 7.3.1.2.13** – Heritage + **Section 7.3.1.2.14** -Fisheries + **Section 7.3.1.2.15** – Tourism + **Section 7.3.1.2.16** – Maritime Industry. The Summary of Risk evaluation in **Section 7.3.1.3** was also updated.
1.3		If water movement in the area is dominated by 'strong tidal regimes' why isn't Santos exploring tidal energy?	The premise of the Dorado Development, as assessed in the OPP, is to extract and produce liquid hydrocarbon fuels from petroleum resources within the Bedout sub-basin. An alternative development concept, such as development of tidal energy resources, is outside the scope of the Dorado OPP. Please note that in accordance with the *OPGGS (Environment) Regulations*, information that is irrelevant to NOPSEMA's decision making criteria such as fundamental objection to oil and gas projects, cannot be considered (NOPSEMA Information Paper # A473111 - Public comment on offshore project proposals).	Santos considers that no modification to the document is necessary.

[65] EPO, control measures and section references were valid for the OPP version submitted at the start of the stage 2 assessment.

#	Name/Organisation	Key Summarised comments on the OPP, including any objections or claims	Santos Assessment of Merit of comment; and response to comment	Changes made to the OPP in response to the comment[65]
1.4		There are "no protected areas of overlap" from an accidental release of hydrocarbons and chemical spills. Comment provider disagreed with this statement, expressing that protected areas will be impacted.	Santos confirms that no protected areas overlap the Dorado Project area, however several protected areas do overlap the Environment that May be Affected (EMBA) from the worst-case credible unplanned hydrocarbon release events. Further explanation of the difference between the Dorado Project area and EMBA are described below: *Project Area (further described in **Section 6.3.1** of the OPP):* The Dorado Development Project Area defines the geographic extent where petroleum activities are planned to take place. The current Project Area is 3,443 km². The Project Area has been designed to avoid potential overlap with any KEFs (such as ancient coastline at 125 m depth contour) and fishing sensitivities (such as pearl oyster). *EMBA (further described in **Section 3.1.1** of the OPP)* The EMBA is determined by the combined spatial extent of impacts and risks of Dorado Phase 1 planned activities and unplanned events. For the Dorado OPP the EMBA represents the largest possible spatial extent for the worst-case credible spill events modelled. The protected areas that occur within the EMBA are detailed in section 3.4.2 of the OPP and risk assessed in Section 7.3 of the OPP. As a summary protected areas in the EMBA include: + 18 Commonwealth Australian marine marks (AMPs); + 14 Western Australian marine protected areas; + 14 Western Australian terrestrial protected areas; and + six wetlands of international importance (Ramsar wetlands).	Santos considers that no modification to the document is necessary.
1.5		The impacts to a number of threatened and migrator species are not adequately mitigated, with no effort to explain the mitigation. The project will have significant environmental impact on these species whether passing through the project boundary or reside within it.	A suite of controls have been included in the OPP to mitigate the risk of an accidental release of hydrocarbons to the environment and matters of MNES, examples include: + The WHP, FPSO and MODU(s) will maintain navigation aids to facilitate identification by other users (e.g. radar response beacons). + Source control emergency response plans in place for all drilling activities. + Accepted Oil Pollution Emergency Plans in place for all Dorado Development activities. A full list of controls is listed in **Section 8.2** of the OPP. While the first priority is always to implement measures to prevent an accidental release of hydrocarbons, there are a range of mitigations that can be applied in the event of an unplanned hydrocarbon spill that can greatly reduce the impacts of the spill, and may eliminate impacts to key environmental receptors. The level of impact reduction achieved through effective mitigation for an accidental release of hydrocarbons from Dorado Phase 1 is described in the demonstration of acceptability in **Section 7.3.1.4** of the OPP.	Santos considers that no modification to the document is necessary.
1.6		With endangered animals listed as breeding in the project area, combined with known science behind global warming, this project should not proceed.	The project area is not within any Biologically Important Areas (BIA) for the Humpback whale, with the closest calving BIA 380 kilometres from the project area, so breeding in the project area is unlikely. This assertion is supported by migration data presented in Thums et al. (2018), which shows only a small number of migrating individuals will traverse the Project Area (Figure 13-4 of the OPP). This migration data, collected over 2008, 2009 and 2011 for tagged humpback whales, shows there are no migration paths that overlap with the Project Area.	Santos considers that no modification to the document is necessary.

#	Name/Organisation	Key Summarised comments on the OPP, including any objections or claims	Santos Assessment of Merit of comment; and response to comment	Changes made to the OPP in response to the comment[65]
			Seabirds are common around the islands and Pilbara coast beyond the Project Area. There are two seabird breeding BIAs which intersect the Project Area: + lesser frigatebird (overlaps the WHP); and + brown booby (19 km from the WHP). Both of these species, along with other seabird species, are expected to forage within the Project Area. The lesser frigatebird, and brown bobby which are known to breed on small remote tropical islands (Bedout Island), are very unlikely to interact with the Well Head Platform. As per Table 8-1 of the OPP, controls will be applied to reduce the likelihood of interaction of birds with the project (for example lighting design). When considering the limited interaction of protected animals designated as endangered MNES within the Project Area, combined with the application of control measures (Table 8-1 of the OPP) to mitigate environmental impacts, Santos considers the impacts to be acceptable.	
			Regarding impacts from warming to 1.5 degrees, Dorado Phase 1 will be developed in a manner that is compliant with Australia's NDC emissions reduction targets as a party to the Paris Agreement. Demonstration that impacts from Dorado Phase 1 GHG emissions are acceptable is addressed in Section 7.2.6.8 of the OPP.	
1.7		Mitigation such as reporting a vessel strike with an endangered Southern Right Whale is not mitigation. Mitigation should not be developed after the incident.	The assessment of impacts and risks from vessel interactions with marine fauna predicts the risk to be very low (Section 7.4 of the OPP), with no adverse effect on species populations. Management of the risk of vessel interactions with marine fauna is consistent with conservation advice and recovery plans that identify vessel strike as a threat. As per the management controls specified in Table 8-1 of the OPP, all vessels will adhere to the requirements of the EPBC Regulations Part 8.1 – Interacting with cetaceans, (except in emergency conditions or when manoeuvring is not possible), which include: + Implement a caution zone of 150 m for dolphins and 300 m for whales, + Vessels will not knowingly approach closer than 50 m to a dolphin 100 m to a whale (i.e. no approach zone), + Make sure a vessel does not drift or approach within 50 m of a dolphin or 100 m of a whale, + Vessels will not knowingly travel more than 6 knots within the caution zone of a dolphin or whale, and + There will not knowingly be no more than three vessels within 300 m of a whale (i.e. caution zone). Outside of the above mitigations, the requirement to report a marine-fauna vessel strike incident is an incident reporting requirement, not a mitigation.	Santos considers that no modification to the document is necessary.
1.8		We know that noise in the ocean is impacting marine life and their ability to survive. Commentor provided several links to articles relating to Noise impacts on MNES. The most	Noise modelling has been used to quantify the environmental impacts anticipated from the Dorado Project in OPP Attachment 10. Potential noise-related impacts will be concentrated around the WHP and FPSO	Santos considers that no modification to the document is necessary.

#	Name/Organisation	Key Summarised comments on the OPP, including any objections or claims	Santos Assessment of Merit of comment; and response to comment	Changes made to the OPP in response to the comment[65]
		obvious impact is the link between military sonar and seismic survey detonations and deafness, mass strandings, and deaths of marine mammals.	locations during the installation and operations stages, which will be temporary and of short duration. The Project area does not include critical habitat (Biologically Important Areas) for threatened or migratory EPBC listed species that may be impacted by underwater noise, such as cetaceans and marine turtles (see OPP Section 7.5.2). Permanent Threshold Shift (PTS) impacts to threatened and migratory fauna could only credibly occur during piling and vertical seismic profiling. Potential PTS impacts will be limited to the area in the immediate vicinity of the piling or vertical seismic profiling source. Temporary Threshold Shift (TTS) and behavioural disturbance may occur at greater distances, but have much lower potential for significant impacts to MNES. Santos' management of underwater noise emissions is aligned to industry practices and relevant requirements, for example the adaptive management of piling and vertical seismic profiling activities aligns with EPBC Act Policy Statement 2.1 - Interaction between offshore seismic exploration and whales (full controls for acoustic emissions are specified in Table 8-1 of the OPP). Santos has experience in effectively implementing these controls for other petroleum developments. These management practices are aligned to relevant conservation advice and recovery plans for threatened and migratory species. While impacts to individual fish may occur, these are expected to consist of TTS and behavioural responses that are temporary. The referenced publications and articles on underwater noise impacts on marine life are noted. Santos consults a wide range of peer-reviewed published literature on noise impacts to marine life to ensure underwater noise environmental impact assessment are informed by peer-reviewed, published science. The Underwater Noise Impacts on Marine Fauna technical appendix captured in **Appendix 12** of the OPP reviews a considerable range of literature relevant to the noise impacts from the Dorado Project (VSP, piling, drilling and vessel operations), to support the acceptability assessment.	
2	Commentor # 2	Regarding gas lift and flash gas compression system for Dorado FPSO; it would be more environmental friendly to have an electrical motor driven compressors. This however will require a larger capacity of power generation system.	During the early engineering phase, Santos did consider electric motors as alternative to gas turbines for the reinjection compressors and flash gas compressors. Electric motor drives were selected for flash gas compressors (*3) and gas driven turbines were selected for the reinjection compressors (*2). The assessment concluded that the electric motor drive for the reinjection compressors would require an additional gas-fired power generation turbine, which would pose unacceptable inefficiencies associated with converting turbine power into electricity and electricity back into rotating power. The reinjection compressor power load requirement closely equates to the available power of a single turbine, therefore it is a good match with regard to efficiency.	Santos considers that no modification to the document is necessary.
3.1	Commentor # 3	EPO4 and other relevant EPO's which refer to 'substantial' are not specific enough, It allows for impact beyond 95%, but does not say to what extent - e.g. 80% species protection limit or 50% species protection limit for example. This should be bounded to a reasonable extent.	+ EPO 4 is considered appropriate, and specific enough. The EPO is bounded by physical extent (i.e. 1 km from the discharge source), and the definition of "substantial" resides in the footnote, describing: - Substantial impacts are defined as an exceedance of the 95% species protection levels for water quality or the default guideline value (high) value for sediments for contaminants in the PW derived from either Australian and New Zealand	+ EPO 7 has been updated in **Section ES-8, Section 7.2.5.3** and **Section 8.2.2** of the OPP.

Santos

#	Name/Organisation	Key Summarised comments on the OPP, including any objections or claims	Santos Assessment of Merit of comment; and response to comment	Changes made to the OPP in response to the comment[65]
			guidelines for fresh and marine water quality (Commonwealth of Australia and New Zealand Government 2018) or discharge-specific whole effluent toxicity testing result using methodology aligned with the guidelines. + EPO 7 has been updated as follows: No impacts from Dorado Phase 1 to commercial fish stocks that occur within the Project Area and are important to the following fisheries: - Pilbara Trap Managed Fishery; - Pilbara Fish Trawl Interim Managed Fishery; - Pilbara Line Fishery; - Mackerel Managed Fishery (Area 2)	
3.2		EPO8 is not specific enough.	EPO 8 is worded intentionally to ensure there is a broad link between management and regulation of Dorado Phase 1 Scope 1 emissions and Australia's commitment and emissions reduction targets as a party to the Paris Agreement. By design, the Paris Agreement incorporate adaptive management provisions to evolve over time as progress is made against emissions reduction targets and temperature reduction objectives, which may mean that the Australian Government's regulation of Dorado Phase 1 GHG emissions may also evolve over time.	Santos considers that no modification to the document is necessary
3.3		EPO9 is not specific enough.	EPO 9 is considered appropriate by committing to reduce direct (Scope 1) GHG emissions to ALARP and acceptable levels because this approach drives facility design and operations to reduce emissions to as low as reasonably practicable, rather than adhering to a prescribed limit. It also allows adoption of future advances in emissions reduction technologies, that may not be considered if the EPO is limited to a prescribed emissions performance limit.	Santos considers that no modification to the document is necessary
3.4		EPO10 is not specific enough nor do CM20, 21, 22, 34 to demonstrate impacts from GHG will be reduced to acceptable levels.	+ EPO10 has been updated to better articulate intent, as follows: Dorado Development oil sale agreements require that the product is sold into a country that has ratified the Paris Agreement and is implementing controls to reduce national emissions in line with Paris Agreement climate change objectives. + CM20 has been removed as the economic viability of the Dorado Project is not relevant to management of environmental risk and outside the scope of OPP decision criteria under the *OPGGS (Environment) Regulations* Demonstration that GHG emissions have been reduced to acceptable levels is addressed in Section 7.2.6.8. CM21 is linked to acceptability through 'internal context' acceptability criteria, and CM22 is linked to 'other relevant requirements' acceptability criteria. CM34 has been deleted due to duplication with CM21 and CM38.	+ EPO 10 has been updated in **Section ES-8, Section 7.2.6** and **Section 8.2.2** of the OPP. + CM 20 and CM34 have been removed from **Section ES-8, Section 7.2.6 and Section 8.2.2** of the OPP.
3.5		CM15 is not acceptable - it should meet the no flaring during routine operations principle. Ref: https://www.worldbank.org/en/programs/zero-routine-flaring-by-2030	+ CM15 has been updated as follows: Limit planned flaring to operation of the flare pilot during routine operations.	CM15 has been updated in **Section ES-8, Section 7.2.4, Section 7.2.6, Section 7.2.7** and **Section 8.2.2** of the OPP.
3.6		CM38 does not show a continuous improvement process which will reduce GHG emissions to ALARP or acceptable levels on an ongoing basis.	+ CM38 has been further strengthened to include a clear commitment to establish a GHG management plan for operation of the facilities, that includes a continuous cycle for monitoring, evaluating, and	CM38 has been replaced by CM35 in the revised OPP, refer to updates in **Section ES-8, Section 7.2.4, Section 7.2.6, Section 7.3.7** and **Section 8.2.2** of the OPP.

#	Name/Organisation	Key Summarised comments on the OPP, including any objections or claims	Santos Assessment of Merit of comment; and response to comment	Changes made to the OPP in response to the comment[65]
			implementing improvements to minimise GHG emission to ALARP and acceptable levels over the life of field operations, as follows: - Dorado Phase 1 will implement a GHG management plan that incorporates an adaptive management approach that facilitates a continuous cycle of monitoring, evaluating, and implementing improvements to minimise GHG emission to ALARP and acceptable levels over the life of field operations including: o Evaluation of emissions monitoring data and ensuring the implemented controls deliver predicted emission reductions, o Seeking new and relevant data/information from external sources relevant to GHG emission management including Commonwealth legislation or policy, o Ensuring effectiveness of internal processes and procedures to reduce and manage GHG emissions, o Responding to changes from detailed engineering outcomes or Paris Agreement updates, o Implementing corrective actions identified from the above.	
3.8		CM39 does not achieve either NZE by 2040 or show how scope 1,2 and 3 emissions reach NZE by 2040. CCS alone can not achieve this. 21MTpa CO2-e emissions are outlined within the Santos 2020 climate change report. Please demonstrate how the Dorado scope 3 emissions will be reduced to net zero by 2040 as a part of this development impact assessment.	+ Elements of CM39 have been incorporated into CM21. CM39 has been deleted. CM21 includes a clear commitment by Santos to achieve NZE by 2040 for scope 1 and 2. As outlined in Santos' 2021 Climate Change report, Santos' credible roadmap to NZE 2040 does not rely on CCS alone and includes a combination of nature based offsets, energy efficiency improvements, CCS, electrification and transition to cleaner fuels such as hydrogen. As discussed in Section 7.2.6.7.1, Scope 3 emissions are outside the control of Santos, as further confirmed by a recent ruling in the NSW Land and Environment Court for the Santos Narrabri Project (Mullaley Gas and Pipeline Accord Inc v Santos NSW (Eastern) Pty Ltd, 2021). Notwithstanding that Scope 3 are outside the direct control of Santos, Santos has committed to only sell Dorado product into a country that has ratified the Paris Agreement and is implementing controls to reduce national emissions in line with Paris Agreement climate change objectives (see EPO10), with the Paris Agreement being the established international framework to manage each countries scope 1 and 2 emissions in line with NDC emissions reduction targets. As such Scope 3 emissions are not within the scope of Santos' NZE by 2040 commitment.	+ CM21 has been replaced by CM20 in the revised OPP, refer to updates in **Section ES-8, Section 7.2.6** and **Section 8.2.2** + CM39 has been removed from **Section ES-8, Section 7.2.6** and **Section 8.2.2**.
3.8		There are material residual impacts to MNES and there supporting habitats which will occur as a result of this development (including indirect impacts from climate change). In addition, the project does not meet the principles of ecologically sustainable development at the moment. It is clearly inconsistent with these as demonstrated by the 153 (not 150 as stated in the OPP main text) MtCO2-e (about 30% Australians total annual emissions) scope 3 emissions alone emitted during this first phase of the project (not even contemplating emissions from a potential future gas project).	Residual impacts to MNES from the Projects contribution to climate change have been assessed at a species and ecological community level in 7.2.6.6, and further assessed within consideration for principles of ESD in 7.2.6.7. In broad terms, the Project will be developed in manner that is compliant with Australia's NDC emissions reduction targets as a party to the Paris Agreement to limit global temperature increase to less than 2°C, thereby ensuring that residual impacts to MNES are limited to acceptable levels. It is misleading to represent the Project's Scope 3 emissions as ~30% of Australia's global emissions when Scope 3 emissions represent emissions	Santos considers that no modification to the document is necessary

#	Name/Organisation	Key Summarised comments on the OPP, including any objections or claims	Santos Assessment of Merit of comment; and response to comment	Changes made to the OPP in response to the comment[65]
			from end use that will occur internationally outside of Australia. Section 7.2.6.5.2. presents a more meaningful comparison of Dorado's Scope 1 and Scope 3 emissions as follows: the estimated total annual average scope 1 and scope 3 CO_{2-e} emissions from all stages of Dorado Phase 1 equate to 0.022% of the 2019 global emissions from fossil fuels, and 0.024% and 0.056% of the predicted 2040 world energy-related CO_{2-e} emissions under the IEA Stated Policies Scenario and the Sustainable Development Scenario respectively.	
3.9		On this basis, I believe it it unacceptable for this development to proceed without a clear demonstrated net positive impact on biodiversity in line with UN sustainable development goals (13, 14 and 15). This should be measured through independent methods such as accounting for nature or other recognised standards and have an appropriate level of independent oversight accordingly.	Comments about the Project demonstrating a net positive biodiversity impact in line with UN Sustainable Development Goals are noted, but not relevant to OPP decision or acceptance criteria under the *OPGGS (Environment) Regulations* or are otherwise already addressed via the *EPBC Act*, and are not considered any further.	Santos considers that no modification to the document is necessary
3.10		Santos as a part of this project should commit to actions which demonstrate how Santos will achieve net zero by 2040 and probably interim targets for Dorado specially as well - such as 2030 or 2035.	As outlined in a response to an earlier comment, Santos has outlined a roadmap to NZE 2040 in its 2021 Climate Change report which includes a combination of measures such as nature based offsets, energy efficiency improvements, CCS, electrification and transition to cleaner fuels such as hydrogen. In 2021, Santos also set three new 2030 emissions reduction targets: + reducing absolute scope 1 and scope 2 emissions and emissions intensity from 2019-2020 levels by 26% to 30% by 2030*, in keeping with Australia's Paris Agreement 2030 emissions reduction target; + carbon capture and storage technology used to accelerate the economic feasibility of clean hydrogen and delivering step change in emissions reduction by 2030; and + actively working with customers to reduce their scope 1 and scope 2 emissions by more than one million tonnes of CO2-e/a by 2030 through direct switching to cleaner fuels. * Baseline is defined as Santos' net share of Scope 1 and 2 emissions, in mtCO2e, from financial year 19/20 production volumes, adjusted to include Bayu-Undan and DLNG at 68.4% for full baseline year.	Santos considers that no modification to the document is necessary
3.11		The project scope reinjects gas from the reservoir. But makes no assessment at this point for potential cumulative impacts of GHG emissions in the eventuality from additional scope 1 and 3 emissions from this potential future development. Confirmation now as to potential cumulative impacts through strategic impact assessment should be carried out now. Will gas recovery occur in future or not?	The Dorado OPP clearly states the development premise is for liquids production and gas reinjection only (with potential for future tie-backs). A potential future Stage 2 gas development is out of scope for this OPP.	Santos considers that no modification to the document is necessary

Executive Summary

Santos WA Northwest Pty Ltd (referred to herein as Santos) are proposing to develop the Dorado oil field, on the North West Shelf of Western Australia. Referred to as the Dorado Development, the project will include a Well Head Platform (WHP) and a Floating Production Storage and Offloading (FPSO) facility.

During the life of the field, Santos may be required to conduct a walk-away Vertical Seismic Profiling (VSP) survey centred on the WHP. This modelling study provides the basis to assess the effects of noise on marine mammals, sea turtles, fish (adults, larvae, eggs), plankton, sponges and corals. The modelling scenarios for the walk-away VSP considered a single 1200 in^3 array suspended at 5 m from the sea surface and towed in a spiral pattern increasing in distance from the WHP. Modelling assessed both individual impulses and multiple impulses within two 24 h periods to determine SEL_{24h}.

The modelling methodology considered source directivity and range-dependent environmental properties in each of the areas assessed. Estimated underwater acoustic levels are presented as sound pressure levels (SPL, L_p), zero-to-peak pressure levels (PK, L_{pk}), peak-to-peak pressure levels (PK-PK; $L_{pk\text{-}pk}$), and either single-impulse (i.e., per-pulse) or accumulated sound exposure levels (SEL, L_E) as appropriate for different noise effect criteria. A conservative sound speed profile that would be most supportive of sound propagation conditions for any time of year was defined and applied to all modelling.

The SEL_{24h} is a cumulative metric that reflects the dosimetric impact of noise levels within 24 hours based on the assumption that an animal is consistently exposed to such noise levels at a fixed position. Where the corresponding SEL_{24h} radii are larger than those for peak pressure criteria, they often represent an unlikely worst-case scenario. More realistically, marine mammals, fish and sea turtles would not stay in the same location for 24 hours (especially in the absence of location-specific habitat, such as reef), but rather a shorter period, depending upon their behaviour and the proximity and movements of the source. Therefore, a reported radius for SEL_{24h} criteria does not mean that marine fauna travelling within this radius of the source will be impaired, but rather that an animal could be exposed to the sound level associated with impairment (either permanent threshold shift (PTS) or temporary threshold shift (TTS)) if it remained in that location for 24 hours.

The analysis considered the distances away from the VSP source at which several effects criteria or relevant sound levels were reached. The results are summarised for the representative single-impulse site and accumulated SEL scenarios in Tables 1–4. The impact criteria for impairment of marine mammals, fish and sea turtles use dual metrics (PK and SEL_{24h}), and the longest distance associated with either metric is required to be applied, and thus is presented in this summary.

Marine mammals

Table 1. Maximum (R_{max}) horizontal distances (in km) from modelled site or within SEL_{24h} modelled scenario to behavioural response, TTS and PTS thresholds for marine mammals.

Hearing group	**Modelled distance (in km) to effect threshold (R_{max})**		
	Behavioural response[1]	Impairment: TTS[2]	Impairment: PTS[2]
Low-frequency (LF) cetaceans	3.78	15.0	3.4
High-frequency (HF) cetaceans		-	-
Very-high-frequency (VHF) cetaceans		1.95	-

[1] Noise exposure criteria: NOAA (2019)
[2] Noise exposure criteria: Southall et al. (2019)
A dash indicates the threshold was not reached within the limits of the modelling resolution (20 m).

Sea turtles

Table 2. Maximum (R_{max}) horizontal distances (in km) from modelled site or within SEL_{24h} modelled scenario to behavioural response, TTS and PTS thresholds for sea turtles.

Hearing group	Modelled distance (in km) to effect threshold (R_{max})			
	Behavioural response[1]	Behavioural disturbance[2]	Impairment: TTS[3]	Impairment: PTS[3]
Turtles	1.99	0.72	2.92	0.03

[1] Noise exposure criteria: NSF (2011)
[2] Noise exposure criteria: McCauley et al. (2000b)
[3] Noise exposure criteria: Finneran et al. (2017)

Fish, fish eggs, and fish larvae

This modelling study assessed the ranges for the quantitative guidelines based on Popper et al. (2014) and considered both PK (seafloor and water column) and SEL_{24h} metrics associated with mortality and potential mortal injury as well as impairment in the following groups:

- Fish without a swim bladder (also appropriate for sharks in the absence of other information)
- Fish with a swim bladder that do not use it for hearing
- Fish that use their swim bladders for hearing
- Fish eggs and fish larvae

Table 3. Summary of maximum fish, fish eggs, and larvae injury and TTS onset distances for single impulse and SEL_{24h} modelled scenarios, maximum-over-depth.

Relevant hearing group	Effect criteria	Metric associated with longest distance to criteria	R_{max} (km)
Fish: No swim bladder	Injury	PK	0.03
	TTS	SEL_{24h}	4.65
Fish: Swim bladder not involved in hearing and Swim bladder involved in hearing	Injury	PK	0.07
	TTS	SEL_{24h}	4.65
Fish eggs, and larvae	Injury	PK	0.07

Table 4. Summary of maximum fish TTS onset distances for SEL_{24h} modelled scenarios, seafloor receptors.

Relevant hearing group	Effect criteria	Scenario 1	
		Metric associated with longest distance to criteria	R_{max} (km)
Fish: No swim bladder	TTS	SEL_{24h}	4.55

Relevant hearing group	Effect criteria	Scenario 1	
		Metric associated with longest distance to criteria	R_{max} (km)
Fish: Swim bladder not involved in hearing and Swim bladder involved in hearing			
Fish eggs, and larvae			

Sponges and Coral

To assist with assessing the potential effects on these receptors, the following have been determined:

- Sponges and coral: The PK sound level at the seafloor directly underneath the VSP source was estimated at the single impulse modelling site and did not reach the sound level of 226 dB re 1 µPa PK for sponges and corals (Heyward et al. 2018);

1. Introduction

JASCO Applied Sciences (JASCO) performed a modelling study of underwater sound levels associated with the development of the Dorado oil field, on the North West Shelf of Western Australia. The Dorado Development will include a Well Head Platform (WHP) and a Floating Production Storage and Offloading (FPSO) facility.

During the life of the field, Santos may be required to conduct a walk-away Vertical Seismic Profiling (VSP) survey centred on the WHP, which could take up to 10 days to complete. The modelling scenarios for the walk-away VSP considered a single 1200 in^3 array suspended at 5 m from the sea surface and towed in a spiral pattern increasing in distance from the WHP. Modelling assessed both individual impulses and multiple impulses within two 24 h periods to determine SEL24h. The scenarios included tight spirals close to the WHP, and larger spirals further away from the WHP An overview of the modelled area is shown in Figure 1. The geographic coordinates for the single impulse modelled site are provided in Table 5.

This study specifically assessed distances from the considered operations to where underwater sound levels reached thresholds corresponding to various levels of impact to marine fauna. The fauna considered in this study included marine mammals, sea turtles, fish (including fish eggs and larvae), plankton, sponges and corals. Due to the variety of species considered, there are several different thresholds for evaluating effects, including: mortality, injury, temporary reduction in hearing sensitivity, and behavioural disturbance.

The modelling methodology considered source directivity and range-dependent environmental properties. Estimated underwater acoustic levels are presented as sound pressure levels (SPL, L_p), zero-to-peak pressure levels (PK, L_{pk}), and either single-impulse (i.e., per-strike) or accumulated sound exposure levels (SEL, L_E) as appropriate for different noise effect criteria for impulsive noise sources.

As the walk-away VSP survey could take place at any time in the year, a conservative water column sound speed profile (i.e., the profile leading to the longest acoustic propagation) was selected for modelling (July, Appendix D.4.2). The seabed vicinity of the modelled sites consists of a layer of unconsolidated fine sandy sediment underlain by a package of carbonate rock with various degrees of lithification, but likely increasing in cementation/lithification with depth.

Table 5. Location details for the single impulse modelled site.

Site	Location Description	Latitude (S)	Longitude (E)	MGA (GDA94), Zone 50		Water depth (m)
				X (m)	*Y* (m)	
1	WHP	19° 01' 38.0010"	118° 44' 36.7440"	683500	7895250	91

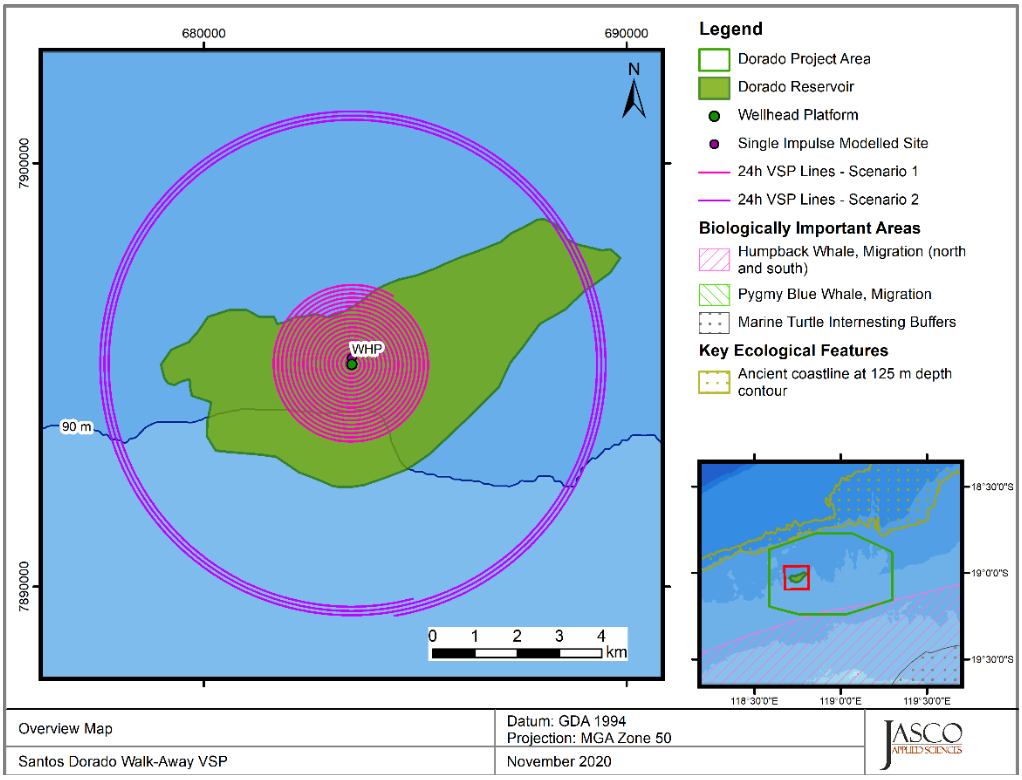

Figure 1. Project overview map showing single impulse site and 24 h SEL modelling scenarios

2. Noise Effect Criteria

The perceived loudness of sound, especially impulsive noise such as from seismic airguns, is not generally proportional to the instantaneous acoustic pressure. Rather, perceived loudness depends on the pulse rise-time and duration, and the frequency content. Several sound level metrics, such as PK, SPL, and SEL, are commonly used to evaluate noise and its effects on marine life (Appendix A.1). The period of accumulation associated with SEL is defined, with this report referencing either a “per pulse” assessment or over 24 h. Appropriate subscripts indicate any applied frequency weighting; unweighted SEL is defined as required. The acoustic metrics in this report reflect the updated ISO standard for acoustic terminology, ISO/DIS 18405:2017 (2017).

Whether acoustic exposure levels might injure, impair or disturb marine fauna is an active research topic. Since 2007, several expert groups have developed SEL-based assessment approaches for evaluating auditory injury and impairment, with key works including Southall et al. (2007), Finneran and Jenkins (2012), Popper et al. (2014), United States National Marine Fisheries Service (NMFS 2018) and Southall et al. (2019). The number of studies that have investigated the level of behavioural disturbance to marine fauna by anthropogenic sound has also increased substantially.

The following thresholds, guidelines and sound levels for this study were chosen because they represent the best available science, and sound levels presented in literature for fauna with no defined thresholds:

1. Peak pressure levels (PK; L_{pk}) and frequency-weighted accumulated sound exposure levels (SEL; $L_{E,24h}$) from Southall et al. (2019) for the onset of permanent threshold shift (PTS) and temporary threshold shift (TTS) in marine mammals (low-frequency (LF), high-frequency (HF), and very-high-frequency (VHF) cetaceans).
2. Marine mammal behavioural threshold based on the current NOAA (2019) criterion for marine mammals of 160 dB re 1 µPa (SPL; L_p) for impulsive sound sources.
3. Sound exposure guidelines for fish, fish eggs and larvae (including plankton) (Popper et al. 2014).
4. Peak pressure levels (PK; L_{pk}) and frequency-weighted accumulated sound exposure levels (SEL; $L_{E,24h}$) from Finneran et al. (2017) for the onset of PTS and TTS in turtles.
5. Sea turtle behavioural response threshold of 166 dB re 1 µPa (SPL; L_p) (NSF 2011), as applied by the US NMFS, along with a sound level associated with behavioural disturbance 175 dB re 1 µPa (SPL; L_p) (McCauley et al. 2000a, 2000b).
6. Additionally, for comparison to published literature, a no effect sound level for sponges and corals of 226 dB re 1 µPa (PK; L_{pk}), is reported for comparing to Heyward et al. (2018).

The following sections (Sections 2.1–2.2 and Appendix A.1), expand on the thresholds, guidelines and sound levels for marine mammals, fish, fish eggs, fish larvae, sea turtles, benthic invertebrates and humans.

A detailed description of the criteria and the background literature is provided in Lucke and McPherson (2020).

2.1. Marine Mammals

There are two categories of auditory threshold shifts or hearing loss: permanent threshold shift (PTS), a physical injury to an animal’s hearing organs; and Temporary Threshold Shift (TTS), a temporary reduction in an animal’s hearing sensitivity as the result of receptor hair cells in the cochlea becoming fatigued.

To help assess the potential for the possible injury and hearing sensitivity changes in marine mammals, this report applies the criteria recommended by Southall et al. (2019), considering both PTS and TTS. These criteria, along with the applied behavioural criteria (NOAA 2019), are summarised in Tables 6 with descriptions included in Appendix A.3.1 (auditory impairment) and Appendix A.3.2 (behavioural response), with frequency weighting explained in Appendix A.4.

Table 6. Acoustic effects of impulsive noise on marine mammals: Unweighted SPL, SEL_{24h}, and PK thresholds

Hearing group	NOAA (2019)	Southall et al. (2019)			
	Behaviour	PTS onset thresholds* (received level)		TTS onset thresholds* (received level)	
	SPL (L_p; dB re 1 µPa)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	PK (L_{pk}; dB re 1 µPa)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	PK (L_{pk}; dB re 1 µPa)
Low-frequency cetaceans		183	219	168	213
High-frequency cetaceans	160	185	230	170	224
Very-high-frequency cetaceans		155	202	140	196

* Dual metric acoustic thresholds for impulsive sounds: Use whichever results in the largest isopleth for calculating PTS and TTS onset. If a non-impulsive sound has the potential of exceeding the peak sound pressure level thresholds associated with impulsive sounds, these thresholds should also be considered.
L_p denotes sound pressure level period.
$L_{pk,flat}$ denotes peak sound pressure is flat weighted or unweighted.
L_E denotes cumulative sound exposure over a 24 h period.

2.2. Fish, Fish Eggs, and Fish Larvae

In 2006, the Working Group on the Effects of Sound on Fish and Sea Turtles was formed to continue developing noise exposure criteria for fish and sea turtles, work begun by a NOAA panel two years earlier. The Working Group developed guidelines with specific thresholds for different levels of effects for several species groups (Popper et al. 2014). The guidelines define quantitative thresholds for three types of immediate effects:

- Mortality, including injury leading to death,
- Recoverable injury, including injuries unlikely to result in mortality, such as hair cell damage and minor haematoma, and
- TTS.

Masking and behavioural effects can be assessed qualitatively, by assessing relative risk rather than by specific sound level thresholds. However, as these depend upon activity-based subjective ranges, these effects are not addressed in this report and are included in Table 7 for completeness only. Because the presence or absence of a swim bladder has a role in hearing, fish's susceptibility to injury from noise exposure depends on the species and the presence and possible role of a swim bladder in hearing. Thus, different thresholds were proposed for fish without a swim bladder (also appropriate for sharks and applied to whale sharks in the absence of other information), fish with a swim bladder not used for hearing, and fish that use their swim bladders for hearing. Sea turtles, fish eggs, and fish larvae are considered separately.

Impulsive noise from airguns (VSP) is assessed in this study, the relevant effects thresholds from Popper et al. (2014) are listed in Table 7. In general, whether an impulsive sound adversely effects fish behaviour depends on the species, the state of the individual exposed, and other factors.

The SEL metric integrates noise intensity over some period of exposure. Because the period of integration for regulatory assessments is not well defined for sounds that do not have a clear start or end time, or for very long-lasting exposures, an exposure evaluation time must be defined. Southall et al. (2007) defines the exposure evaluation time as the greater of 24 h or the duration of the activity. Popper et al. (2014) recommend a standard period of the duration of the activity; however, the publication also includes caveats about considering the actual exposure times if fish move. The integration time for VSP operations it is over the total number of impulses per day.

Table 7. Guidelines for seismic noise exposure for fish, adapted from Popper et al. (2014).

Type of animal	Mortality and Potential mortal injury	Impairment			Behaviour
		Recoverable injury	TTS	Masking	
Fish: No swim bladder (particle motion detection)	>219 dB SEL_{24h} or >213 dB PK	>216 dB SEL_{24h} or >213 dB PK	>>186 dB SEL_{24h}	(N) Low (I) Low (F) Low	(N) High (I) Moderate (F) Low
Fish: Swim bladder not involved in hearing (particle motion detection)	210 dB SEL_{24h} or >207 dB PK	203 dB SEL_{24h} or >207 dB PK	>>186 dB SEL_{24h}	(N) Low (I) Low (F) Low	(N) High (I) Moderate (F) Low
Fish: Swim bladder involved in hearing (primarily pressure detection)	207 dB SEL_{24h} or >207 dB PK	203 dB SEL_{24h} or >207 dB PK	186 dB SEL_{24h}	(N) Low (I) Low (F) Moderate	(N) High (I) High (F) Moderate
Fish eggs and fish larvae (relevant to plankton)	>210 dB SEL_{24h} or >207 dB PK	(N) Moderate (I) Low (F) Low	(N) Moderate (I) Low (F) Low	(N) Low (I) Low (F) Low	(N) Moderate (I) Low (F) Low

Peak sound pressure level dB re 1 µPa; SEL_{24h} dB re 1µPa^2·s.
All criteria are presented as sound pressure even for fish without swim bladders since no data for particle motion exist.
Relative risk (high, moderate, low) is given for animals at three distances from the source defined in relative terms as near (N), intermediate (I), and far (F).

2.3. Sea turtles

There is a paucity of data regarding responses of turtles to acoustic exposure, and no studies of hearing loss due to exposure to loud sounds. Popper et al. (2014) suggested thresholds for onset of mortal injury (including PTS) and mortality for sea turtles and, in absence of taxon-specific information, adopted the levels for fish that do not hear well (suggesting that this likely would be conservative for sea turtles).

Finneran et al. (2017) presented revised thresholds for sea turtle injury and hearing impairment (TTS and PTS). Their rationale is that sea turtles have best sensitivity at low frequencies and are known to have poor auditory sensitivity (Bartol and Ketten 2006, Dow Piniak et al. 2012). Accordingly, TTS and PTS thresholds for turtles are likely more similar to those of fishes than to marine mammals (Popper et al. 2014).

McCauley et al. (2000a) observed the behavioural response of caged sea turtles—green (*Chelonia mydas*) and loggerhead (*Caretta caretta*)—to an approaching seismic airgun. For received levels above 166 dB re 1 µPa (SPL), the sea turtles increased their swimming activity and above 175 dB re 1 µPa they began to behave erratically, which was interpreted as an agitated state. The 166 dB re 1 µPa level has been used as the threshold level for a behavioural disturbance response by NMFS and applied in the Arctic Programmatic Environment Impact Statement (PEIS) (NSF 2011). In addition the 175 dB re 1 µPa level from McCauley et al. (2000a) is recommended as a criterion for behavioural disturbance. The Recovery Plan for Marine Turtles in Australia (Department of the Environment and Energy et al. 2017) acknowledges the 166 dB re1 µPa SPL reported by McCauley et al. (2000a) as the level that may result in a behavioural response to marine turtles. These thresholds are shown in Table 8.

Table 8. Acoustic effects of impulsive noise on sea turtles: Unweighted SPL, SEL_{24h}, and PK thresholds

Effect type	Criterion	SPL (L_p; dB re 1 µPa)	Weighted SEL_{24h} ($L_{E,24h}$; dB re 1 µPa²·s)	PK (L_{pk}; dB re 1 µPa)
Behavioural response	NSF (2011)	166	NA	
Behavioural disturbance	McCauley et al. (2000b)	175		
PTS onset thresholds* (received level)	Finneran et al. (2017)	NA	204	232
TTS onset thresholds* (received level)			189	226

* Dual metric acoustic thresholds for impulsive sounds: Use whichever results in the largest isopleth for calculating PTS and TTS onset. If a non-impulsive sound has the potential of exceeding the peak sound pressure level thresholds associated with impulsive sounds, these thresholds should also be considered.
L_p denotes sound pressure level period and has a reference value of 1 µPa.
$L_{pk,flat}$ denotes peak sound pressure is flat weighted or unweighted and has a reference value of 1 µPa.
L_E denotes cumulative sound exposure over a 24 h period and has a reference value of 1 µPa²s.

3. Methods

This section describes the methods used to characterise the VSP acoustic sources as well as the acoustic propagation models and frequency ranges considered for estimation of acoustic fields.

The pressure signature of the individual airguns and the composite decidecade-band point-source equivalent directional levels (i.e., source levels) of the 1200 in^3 VSP source suspended at 5 m were modelled with JASCO's Airgun Array Source Model (AASM; Appendix B.1).

Three sound propagation models were used to predict the acoustic field around the VSP source:

- Combined range-dependent parabolic equation and Gaussian beam acoustic ray-trace model (MONM-BELLHOP, 10 Hz to 25 kHz; Appendix C.3).
- FWRAM (5 Hz to 1024 Hz; Appendix C.2).
- Wavenumber integration model (VSTACK, 10 Hz to 1024 Hz).

The models were combined to characterise the acoustic fields at short and long ranges in terms of SEL, SPL, PK, and PK-PK. Appendix C details each model. MONM was used to calculate SEL of a 360° area around the source location. To account for the change in the source orientation as the spiral survey progresses, the orientation of the VSP source was modelled at tow angles encompassing 360° around the source location incremented at 5º.

VSTACK was used to calculate PK and PK-PK transects at the seafloor at close range from the seismic source. FWRAM was used to calculate PK and PK-PK in the entire water column along four selected transects, and to obtain a range dependent conversion factor to estimate SPL from the MONM-BELLHOP SEL results.

3.1. Acoustic Source Model

AASM accounts for the notional pressure signatures of each source element with respect to the effects of surface-reflected signals on bubble oscillations and inter-bubble interactions, the surface-reflected signal (known as surface ghost) is not included in the far-field source signatures. The acoustic propagation models account for those surface reflections, which are a property of the propagating medium rather than the source.

AASM considers:

- Array layout.
- Volume, depth, and firing pressure of each airgun.
- Interactions between different airguns in the array.

The VSP source considered was modelled over AASM's full frequency range, up to 25 kHz; Appendix B.1 details this model.

3.2. Sound Propagation Models

To assess sound levels with MONM-BELLHOP, the sound field modelling calculated propagation losses up to distances at least 80 km from the source, with a horizontal separation of 20 m between receiver points along the modelled radials. The sound fields were modelled with a horizontal angular resolution of $\Delta\theta = 2.5°$ for a total of $N = 144$ radial planes. Receiver depths were chosen to span the entire water column over the modelled areas, from 2 m to a maximum of 350 m, with step sizes that increased with depth. To supplement the MONM results, high-frequency results for propagation loss were modelled using Bellhop for frequencies from 1.6 to 25 kHz. The MONM and Bellhop results were combined to produce results for the full frequency range of interest.

FWRAM was run to 80 km along only four radials for computational efficiency from 5 to 1024 Hz in 1 Hz steps. In the context of VSP source geometry (see Appendix B.2) the along four radials (fore and aft endfire, and port and starboard broadside) for computational efficiency. This was done to compute

SEL-to-SPL conversions (Appendix D.2) but also to quantify water column PK and PK-PK. The horizontal range step was dependent on frequency and ranged from 50 m at lower frequencies to 10 m above 800 Hz.

The maximum modelled range for VSTACK was 1000 m and a variable receiver range increment that increased away from the source, from 10 to 25 m, was used. Received levels were computed at the seafloor.

During a seismic survey, new sound energy is introduced into the environment with each pulse from the seismic source. The vessel towing the airgun was modelled travelling at 2.5 knots, with an overall inter-pulse-interval of 25 m. The modelling for Scenario 1 and Scenario 2 each included 4448 seismic impulses. While some impact criteria are based on the per-pulse energy released, others, such as the marine mammal, turtle and fish SEL criteria used in this report (Section 2) account for the total acoustic energy marine fauna is subjected to over a specified period of time, defined in this report as 24 h. An accurate assessment of the accumulated sound energy depends not only on the parameters of each seismic pulse impulse, but also on the number of impulses delivered in a period and the relative positions of the impulses. Appendix D.3 provides additional details on the methods used to calculate the accumulated sound energy for the considered scenarios.

4. Results

For the results and tables presented below where a dash is used in place of a horizontal distance, these thresholds may or may not be reached due to the discretely sampled radial increments of the modelled sound fields. A dash therefore is an indication that effect levels for the associated metric may only be reached within a very close proximity to a given source.

4.1. Acoustic Source Levels and Directivity

AASM (Section 3.1) was used to predict the horizontal and vertical overpressure signatures and corresponding power spectrum levels for the seismic source, with results provided in Appendix B.2 along with the horizontal directivity plots.

Table 9 shows the PK and per-pulse SEL source levels in the horizontal-plane broadside (perpendicular to the tow direction), endfire (along the tow direction), and vertical directions. The vertical source level that accounts for the “surface ghost” (the out of phase reflected pulse from the water surface) is also presented to make it easier to compare the output of other seismic source models.

Figure B-2 shows overpressure signatures and corresponding power spectrum levels for the source. The signature consists of a strong primary peak, related to the initial release of high-pressure air, followed by a series of pulses associated with bubble oscillations. Most energy was produced at frequencies below 300 Hz. Frequency-dependent peaks and nulls in the spectrum result from interference among airguns in the source and correspond with the volumes and relative locations of the airguns to each other.

Table 9. Far-field source level specifications for the 1200 in^3 source, for a 5 m source depth. Source levels are for a point-like acoustic source with equivalent far-field acoustic output in the specified direction. Sound level metrics are per-pulse and unweighted.

Direction	Peak source pressure level ($L_{S,pk}$; dB re 1 μPa m)	Per-pulse source SEL ($L_{S,E}$; dB 1 $μPa^2m^2s$)	
		10–2000 Hz	2000–25000 Hz
Broadside	244.7	218.5	174.8
Endfire	232.6	217.8	169.5
Vertical	244.7	218.5	178.8
Vertical (surface affected source level)	244.7	220.5	181.9

4.2. Per-Pulse Sound Fields

This section presents the per-pulse sound fields in terms of maximum-over-depth SPL, SEL, PK, and seafloor PK and PK-PK. The different metrics are presented for the following reasons:

- SPL sound fields were used to determine the distances to marine mammal and turtle behavioural thresholds (see Sections 2.1 and 2.3).
- Per-pulse SEL sound fields are used as inputs into the 24 h SEL scenarios, and to place in context the range to 160 dB re 1 µPa^2·s, relevant for the EPBC Act Policy Statement 2.1 (DEWHA 2008).
- PK metrics within the water column are relevant to thresholds and guidelines for marine mammals, sea turtles, fish, fish eggs and larvae (as well as plankton) (Sections 2.1–2.3).
- PK metrics at the seafloor are relevant to guidelines for fish, fish eggs and larvae (Section 2.2) and the sound level for no effect on corals and sponges.

The maximum and 95% distances (calculated as detailed in Appendix D.1) for per-pulse SEL and SPL metrics are presented in Tables 10 and 11. The SPL sound fields, and distances to relevant isopleths can be visualised on the contour map presented in Figure 2. The SPL sound fields are also presented as a vertical slice along the endfire and broadside directions out to 15 km, with the airgun array in the centre (Figure 3).

Maximum distances to PK and PK-PK thresholds were calculated with maximum-over-depth results presented in Table 12, whilst maximum distances to PK thresholds were also calculated at the seafloor (Table 13).

Table 10. Maximum (R_{max}) and 95% ($R_{95\%}$) horizontal distances (in km) from the 1200 in^3 source to modelled maximum-over-depth unweighted per-pulse SEL isopleths from the modelled single impulse site at the WHP.

4.2.1. Sound field maps and graphs

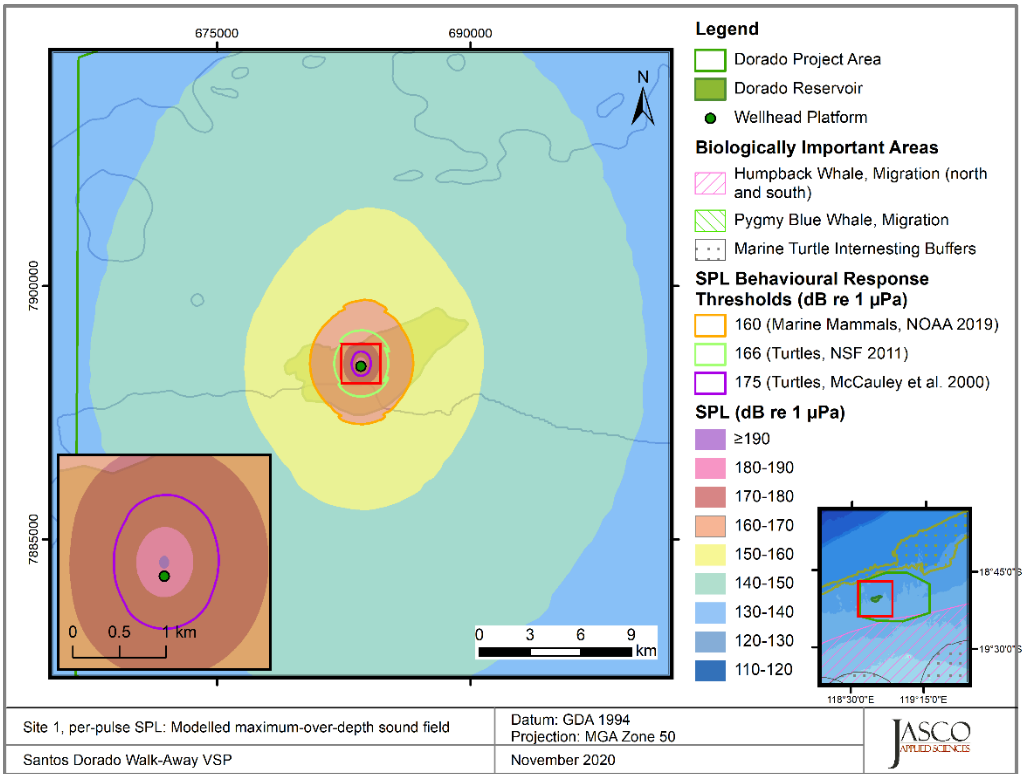

Figure 2. *SPL:* Sound level contour map showing unweighted maximum-over-depth results.

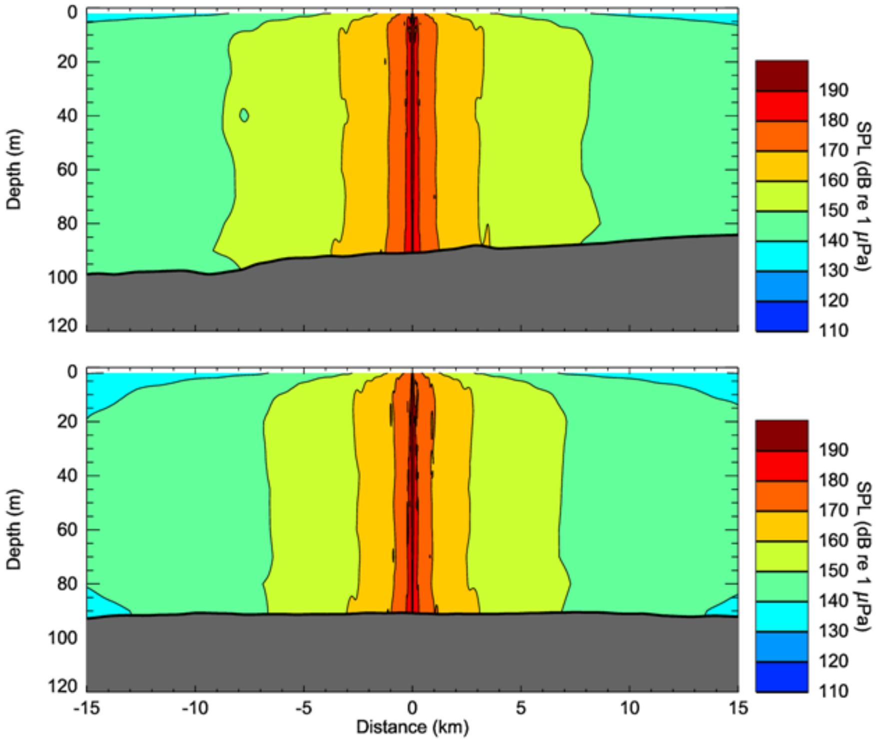

Figure 3. *SPL*: *Vertical sound field slice,* broadside (top) and endfire (bottom).

4.3. Multiple Pulses Sound Fields

This section presents the sound fields in terms of SEL accumulated over 24 hours of survey, for the two modelled SEL_{24h} scenarios. Frequency-weighted SEL_{24h} sound fields were used to estimate the maximum and 95% distances (R_{max} and $R_{95\%}$; calculated as detailed in Appendix D.1) to marine mammals and turtle PTS and TTS thresholds (listed in Table 14), and to estimate maximum distance and the area to injury and TTS thresholds for fish over the entire water column and at the seafloor (Table 15).

The SEL_{24h} sound fields are presented as contour maps in Figures 4 to 7. These figures present the unweighted SEL_{24h} in 10 dB steps, as well as the isopleths corresponding to criteria thresholds. Only contours at ranges larger than the nearfield of the seismic source are rendered.

Table 14. *Marine Mammal and sea turtles*: Maximum (R_{max}) and 95% ($R_{95\%}$) horizontal distances (in km) from the survey lines to permanent threshold shift (PTS) and temporary threshold shift (TTS) thresholds considering 24 h of survey activity.

I, II, III	186	4.65[B]	65.4	2.48[C]	140.6
Seafloor					
I, II, III	186	4.55[B]	63.9	2.4[C]	137.0

Fish I–No swim bladder; Fish II–Swim bladder not involved with hearing; Fish III–Swim bladder involved with hearing.
[A] Radial distance estimated from a shot point unless indicated otherwise.
[B] Radial distance reported from the centre of the WHP.
[C] Radial distance reported from the centre of a set of 24 h scenario tracks unless indicated otherwise.
A dash indicates the threshold was not reached within the limits of the modelling resolution (20 m).
An asterisk indicates that the sound level was not reached.

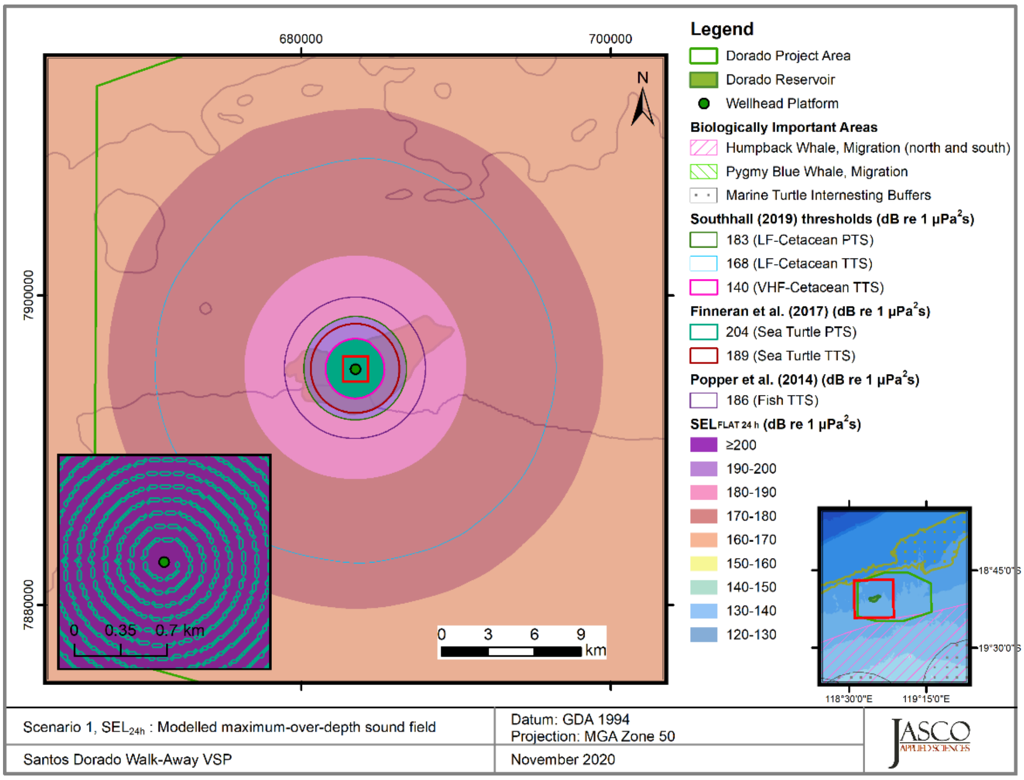

Figure 4. *Scenario 1*: Sound level contour map showing unweighted maximum-over-depth SEL_{24h} results, along with isopleths for low-, and very-high-frequency cetaceans and sea turtles and fish.Thresholds omitted here were not reached or not large enough to display graphically. Refer to Tables 14 and 15 for tabulated radii.

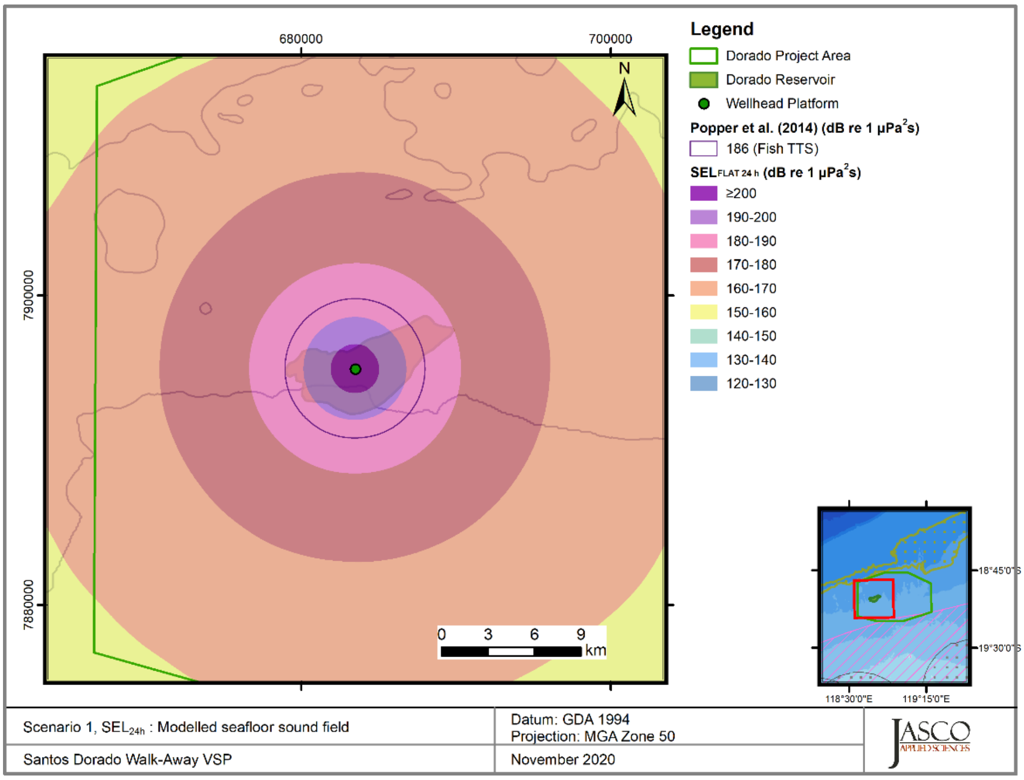

Figure 5. *Scenario 1*: Sound level contour map showing unweighted seafloor SEL_{24h} results, along with isopleths for fish. Where contours are too small to identify on the map refer to the radii in Table 15 for distances. Mortality and recoverable injury thresholds for Fish I were not reached.

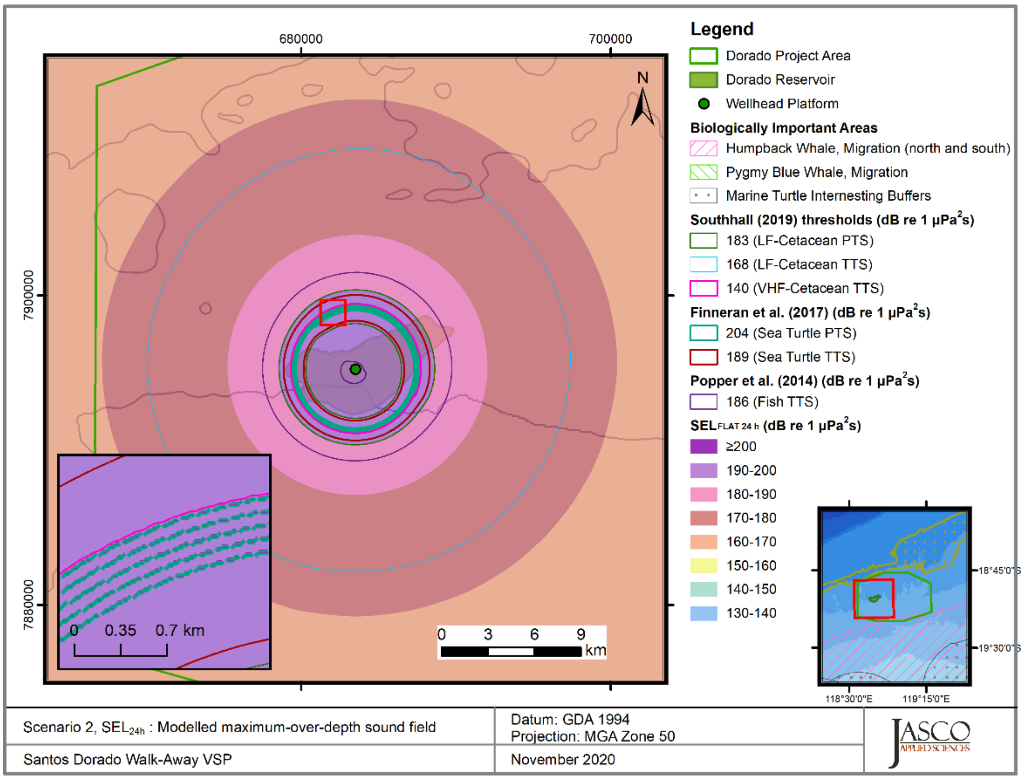

Figure 6. *Scenario 2*: Sound level contour map showing unweighted maximum-over-depth SEL_{24h} results, along with isopleths for low-, and very-high-frequency cetaceans and sea turtles and fish.Thresholds omitted here were not reached or not large enough to display graphically. Refer to Tables 14 and 15 for tabulated radii.

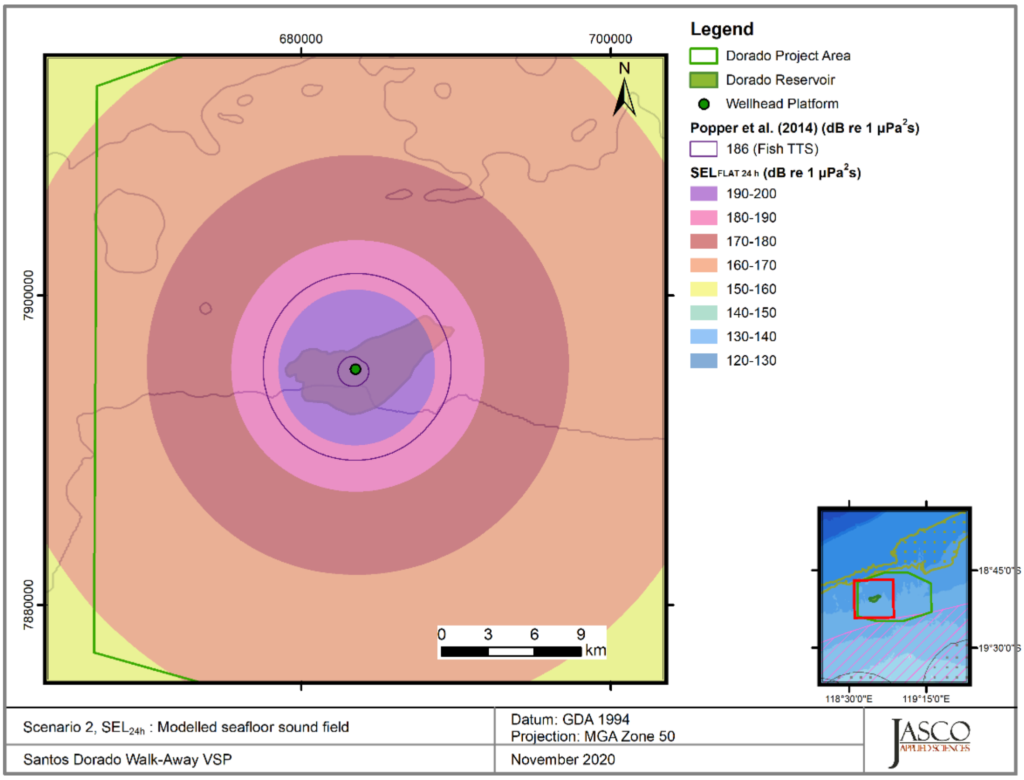

Figure 7. *Scenario 2*: Sound level contour map showing unweighted seafloor SEL_{24h} results, along with isopleths for fish. Where contours are too small to identify on the map refer to the radii in Table 15 for distances. Mortality and recoverable injury thresholds for Fish I were not reached.

5. Discussion and Summary

An analysis of seasonal sound speed profiles, the results of which are presented in Appendix D.4.2, indicated that July was the month most conducive to sound propagation due to the presence of an upward refracting layer near the sea surface; as such it was selected to ensure a conservative estimation of distances to received sound level thresholds. Modelling also accounted for site-specific bathymetric variations (Appendix D.4.1) and local seabed geoacoustic properties (Appendix D.4.3).

As the VSP modelled site was situated on the central North West Shelf, variations in bathymetry were generally gradual within the modelled area. Any variations in the bathymetry had a small effect on the predicted sound field footprints as manifested in the generally symmetric single pulse sound field footprints.

5.1. Ranges to exposure thresholds

For the results and summary tables presented above and below where a dash is used in place of a horizontal distance, these thresholds may or may not be reached. Due to the discretely sampled 20 m radial increments of the modelled sound fields, distances to those levels could not be estimated to the computational resolution of the closest step to the source. It is likely that in the case of per-pulse SPL, SEL, and PK, some thresholds would be reached at distances between the source and the modelled horizontal resolution (20 m); the injury thresholds based on accumulated SEL on the other hand may not be reached at any range due the species specific frequency weighing functions. A dash therefore is an indication that effect levels for the associated metric may only be reached within a very close proximity to a given source, if at all.

This study predicted underwater sound levels associated with the VSP source at the WHP. The underwater sound field was modelled for a 1200 in^3 seismic source array deployed at depth 5 m (Appendix B). The VSP source exhibits minor directivity (Figure 2), with higher levels in the broadside direction.

The accumulated SEL over 24 hours of seismic source operation was modelled considering two representative scenarios with a realistic acquisition pattern for the walk-away VSP – either close to the MODU or further out on the spiral. The modelling predicted the accumulation of sound energy, considering the change in location and the azimuth of the source at each pulse point, which were used to assess distances to the SEL_{24h} based thresholds and guidelines. The results were presented as maps of the accumulated exposure levels and tabulated values of ranges to threshold levels and exposure areas for the given effects criteria (Section 4.3).

5.2. Summary

This section summarises the distances to the noise effect criteria applied in this study (Section 2) for the various fauna groups. The effect criteria for impairment of marine mammals, fish and sea turtles use dual metrics (PK and SEL_{24h}), and the longest distance associated with either metric is required to be applied, and thus is presented in this summary.

The SEL_{24h} is a cumulative metric that reflects the dosimetric impact of noise levels within 24 hours based on the assumption that an animal is consistently exposed to such noise levels at a fixed position. Where the corresponding SEL_{24h} effect radii are larger than those for peak pressure criteria, they often represent an unlikely worst-case scenario. More realistically, marine mammals, fish and sea turtles would not stay in the same location for 24 hours, but rather a shorter period, depending upon their behaviour and the proximity and movements of the source. Therefore, a reported radius for SEL_{24h} criteria does not mean that marine fauna travelling within this radius of the source will be impaired, but rather that an animal could be exposed to the sound level associated with impairment (either PTS or TTS) if it remained in that location for 24 hours.

Marine mammals

Table 16 summarises the distances to effect criteria for marine mammals.

Table 16. Maximum (R_{max}) horizontal distances (in km) from modelled site or within SEL_{24h} modelled scenario to behavioural response, TTS and PTS thresholds for marine mammals (PK values from Table 12 and SEL_{24h} values from Table 14).

Hearing group	Modelled distance (in km) to effect threshold (R_{max})		
	Behavioural response[1]	Impairment: TTS[2]	Impairment: PTS[2]
Low-frequency (LF) cetaceans	3.78	15.0	3.4
High-frequency cetaceans		–	–
Very-high-frequency cetaceans		1.95	–

[1] Noise exposure criteria: NOAA (2019)
[2] Noise exposure criteria: Southall et al. (2019)
A dash indicates the threshold was not reached within the limits of the modelling resolution (20 m).

Sea turtles

Table 17 summarises the distances to effect criteria for sea turtles.

Table 17. Maximum (R_{max}) horizontal distances (in km) from modelled sites or scenarios to behavioural response thresholds and PTS and TTS thresholds for sea turtles (PK values from Table 12 and SEL_{24h} values from Table 14).

Hearing group	Modelled distance (in km) to effect threshold (R_{max})			
	Behavioural response[1]	Behavioural disturbance[2]	Impairment: TTS[3]	Impairment: PTS[3]
Turtles	1.99	0.72	2.92	0.03[C]

[1] Noise exposure criteria: NSF (2011)
[2] Noise exposure criteria: McCauley et al. (2000b)
[3] Noise exposure criteria: Finneran et al. (2017)
[C] Radial distance estimated from the centre impulse point.

Fish, fish eggs, and fish larvae

This modelling study assessed the ranges for quantitative criteria based on Popper et al. (2014) and considered both PK (seafloor and water column) and SEL_{24h} metrics associated with mortality and potential mortal injury as well as impairment in the following groups:

- Fish without a swim bladder (also appropriate for sharks in the absence of other information).
- Fish with a swim bladder that do not use it for hearing.
- Fish that use their swim bladders for hearing.
- Fish eggs and fish larvae.

Tables 18 and 19 summarise the distances to injury criteria for fish, fish eggs and fish larvae along with the relevant metric and the location of the information within this report.

Table 18. Summary of maximum fish, fish eggs, and larvae injury and TTS onset distances for single impulse and SEL_{24h} modelled scenarios (PK values from Table 12 and SEL_{24h} values from Table 15).

Relevant hearing group	Effect criteria	Metric associated with longest distance to criteria	R_{max} (km)
Fish: No swim bladder	Injury	PK	0.03
	TTS	SEL_{24h}	4.65
Fish: Swim bladder not involved in hearing and Swim bladder involved in hearing	Injury	PK	0.07
	TTS	SEL_{24h}	4.65
Fish eggs, and larvae	Injury	PK	0.07

Table 19. Summary of maximum fish TTS onset distances for SEL_{24h} modelled scenarios, seafloor receptors , values from Table 15.

Relevant hearing group	Effect criteria	Scenario 1	
		Metric associated with longest distance to criteria	R_{max} (km)
Fish: No swim bladder	TTS	SEL_{24h}	4.55
Fish: Swim bladder not involved in hearing and Swim bladder involved in hearing			
Fish eggs, and larvae			

Sponges and Coral

To assist with assessing the potential effects on sponges and coral, the PK sound level at the seafloor directly underneath the VSP source was estimated and compared to the no effect sound level of 226 dB re 1 µPa PK for sponges and corals (Heyward et al. 2018); it was not reached (Table 13).

6. Glossary

1/3-octave
One third of an octave. Note: A one-third octave is approximately equal to one decidecade (1/3 oct ≈ 1.003 ddec; ISO 2017).

1/3-octave-band
Frequency band whose bandwidth is one one-third octave. Note: The bandwidth of a one-third octave-band increases with increasing centre frequency.

absorption
The reduction of acoustic pressure amplitude due to acoustic particle motion energy converting to heat in the propagation medium.

acoustic impedance
The ratio of the sound pressure in a medium to the rate of alternating flow of the medium through a specified surface due to the sound wave.

ambient noise
All-encompassing sound at a given place, usually a composite of sound from many sources near and far (ANSI S1.1-1994 R2004), e.g., shipping vessels, seismic activity, precipitation, sea ice movement, wave action, and biological activity.

attenuation
The gradual loss of acoustic energy from absorption and scattering as sound propagates through a medium.

Auditory frequency weighting (auditory weighting function, frequency-weighting function)
The process of band-pass filtering sounds to reduce the importance of inaudible or less-audible frequencies for individual species or groups of species of aquatic mammals (ISO 2017). One example is M-weighting introduced by Southall et al. (2007) to describe "Generalized frequency weightings for various functional hearing groups of marine mammals, allowing for their functional bandwidths and appropriate in characterising auditory effects of strong sounds".

azimuth
A horizontal angle relative to a reference direction, which is often magnetic north or the direction of travel. In navigation it is also called bearing.

bandwidth
The range of frequencies over which a sound occurs. Broadband refers to a source that produces sound over a broad range of frequencies (e.g., seismic airguns, vessels) whereas narrowband sources produce sounds over a narrow frequency range (e.g., sonar) (ANSI/ASA S1.13-2005 R2010).

bar
Unit of pressure equal to 100 kPa, which is approximately equal to the atmospheric pressure on Earth at sea level. 1 bar is equal to 10^5 Pa or 10^{11} µPa.

broadband sound level
The total sound pressure level measured over a specified frequency range. If the frequency range is unspecified, it refers to the entire measured frequency range.

broadside direction
Perpendicular to the travel direction of a source. Compare with endfire direction.

cavitation
A rapid formation and collapse of vapor cavities (i.e., bubbles or voids) in water, most often caused by a rapid change in pressure. Fast-spinning vessel propellers typically cause cavitation, which creates a lot of noise.

cetacean
Any animal in the order Cetacea. These are aquatic, mostly marine mammals and include whales, dolphins, and porpoises.

compressional wave
A mechanical vibration wave in which the direction of particle motion is parallel to the direction of propagation. Also called primary wave or P-wave.

continuous sound
A sound whose sound pressure level remains above ambient sound during the observation period (ANSI/ASA S1.13-2005 R2010). A sound that gradually varies in intensity with time, for example, sound from a marine vessel.

decade
Logarithmic frequency interval whose upper bound is ten times larger than its lower bound (ISO 2006).

decidecade
One tenth of a decade (ISO 2017). Note: An alternative name for decidecade (symbol ddec) is "one-tenth decade". A decidecade is approximately equal to one third of an octave (1 ddec ≈ 0.3322 oct) and for this reason is sometimes referred to as a "one-third octave".

decidecade band
Frequency band whose bandwidth is one decidecade. Note: The bandwidth of a decidecade band increases with increasing centre frequency.

decibel (dB)
One-tenth of a bel. Unit of level when the base of the logarithm is the tenth root of ten, and the quantities concerned are proportional to power (ANSI S1.1-1994 R2004).

endfire direction
Parallel to the travel direction of a source. See also broadside direction.

ensonified
Exposed to sound.

far-field
The zone where, to an observer, sound originating from an array of sources (or a spatially distributed source) appears to radiate from a single point. The distance to the acoustic far-field increases with frequency.

fast-average sound pressure level
The time-averaged sound pressure levels calculated over the duration of a pulse (e.g., 90%-energy time window), using the leaky time integrator from Plomp and Bouman (1959) and a time constant of 125 ms. Typically used only for pulsed sounds.

fast Fourier transform (FFT)
A computationally efficiently algorithm for computing the discrete Fourier transform.

frequency
The rate of oscillation of a periodic function measured in cycles-per-unit-time. The reciprocal of the period. Unit: hertz (Hz). Symbol: *f*. 1 Hz is equal to 1 cycle per second.

hearing group
Groups of marine mammal species with similar hearing ranges. Commonly defined functional hearing groups include low-, high-, and very-high-frequency cetaceans, pinnipeds in water, and pinnipeds in air.

geoacoustic
Relating to the acoustic properties of the seabed.

hearing threshold
The sound pressure level for any frequency of the hearing group that is barely audible for a given individual in the absence of significant background noise during a specific percentage of experimental trials.

hertz (Hz)
A unit of frequency defined as one cycle per second.

high-frequency (HF) cetacean
The functional cetacean hearing group that represents those odontocetes (toothed whales) specialised for high-frequency hearing. Mid-frequency cetaceans from NMFS (2018) are classified as high-frequency cetaceans in Southall et al. (2019).

intermittent sound
A level of sound that abruptly drops to the background noise level several times during the observation period.

impulsive sound
Sound that is typically brief and intermittent with rapid (within a few seconds) rise time and decay back to ambient levels (NOAA 2013, ANSI S12.7-1986 R2006). For example, seismic airguns and impact pile driving.

low-frequency (LF) cetacean
The functional cetacean hearing group that represents mysticetes (baleen whales) specialised for hearing low frequencies.

masking
Obscuring of sounds of interest by sounds at similar frequencies.

median
The 50th percentile of a statistical distribution.

Monte Carlo simulation
The method of investigating the distribution of a non-linear multi-variate function by random sampling of all of its input variable distributions.

mysticete
Mysticeti, a suborder of cetaceans, use their baleen plates, rather than teeth, to filter food from water. They are not known to echolocate, but they use sound for communication. Members of this group include rorquals (Balaenopteridae), right whales (Balaenidae), and grey whales (*Eschrichtius robustus*).

non-impulsive sound
Sound that is broadband, narrowband or tonal, brief or prolonged, continuous or intermittent, and typically does not have a high peak pressure with rapid rise time (typically only small fluctuations in decibel level) that impulsive signals have (ANSI/ASA S3.20-1995 R2008). For example, marine vessels, aircraft, machinery, construction, and vibratory pile driving (NIOSH 1998, NOAA 2015).

octave
The interval between a sound and another sound with double or half the frequency. For example, one octave above 200 Hz is 400 Hz, and one octave below 200 Hz is 100 Hz.

odontocete
The presence of teeth, rather than baleen, characterizes these whales. Members of the Odontoceti are a suborder of cetaceans, a group comprised of whales, dolphins, and porpoises. The skulls of

toothed whales are mostly asymmetric, an adaptation for their echolocation. This group includes sperm whales, killer whales, belugas, narwhals, dolphins, and porpoises.

parabolic equation method
A computationally efficient solution to the acoustic wave equation that is used to model transmission loss. The parabolic equation approximation omits effects of back-scattered sound, simplifying the computation of transmission loss. The effect of back-scattered sound is negligible for most ocean-acoustic propagation problems.

peak pressure level (PK)
The maximum instantaneous sound pressure level, in a stated frequency band, within a stated period. Also called zero-to-peak pressure level. Unit: decibel (dB).

peak-to-peak pressure level (PK-PK)
The difference between the maximum and minimum instantaneous pressure levels. Unit: decibel (dB).

percentile level, exceedance
The sound level exceeded *n*% of the time during a measurement.

permanent threshold shift (PTS)
A permanent loss of hearing sensitivity caused by excessive noise exposure. PTS is considered auditory injury.

pinniped
A common term used to describe all three groups that form the superfamily Pinnipedia: phocids (true seals or earless seals), otariids (eared seals or fur seals and sea lions), and walrus.

point source
A source that radiates sound as if from a single point (ANSI S1.1-1994 R2004).

pressure, acoustic
The deviation from the ambient hydrostatic pressure caused by a sound wave. Also called overpressure. Unit: pascal (Pa). Symbol: *p*.

pressure, hydrostatic
The pressure at any given depth in a static liquid that is the result of the weight of the liquid acting on a unit area at that depth, plus any pressure acting on the surface of the liquid. Unit: pascal (Pa).

received level (RL)
The sound level measured (or that would be measured) at a defined location.

rms
root-mean-square.

signature
Pressure signal generated by a source.

sound
A time-varying pressure disturbance generated by mechanical vibration waves travelling through a fluid medium such as air or water.

sound exposure
Time integral of squared, instantaneous frequency-weighted sound pressure over a stated time interval or event. Unit: pascal-squared second ($Pa^2·s$) (ANSI S1.1-1994 R2004).

sound exposure level (SEL)
A cumulative measure related to the sound energy in one or more pulses. Unit: dB re 1 µPa²·s. SEL is expressed over the summation period (e.g., per-pulse SEL [for airguns], single-strike SEL [for pile drivers], 24-hour SEL).

sound exposure spectral density
Distribution as a function of frequency of the time-integrated squared sound pressure per unit bandwidth of a sound having a continuous spectrum (ANSI S1.1-1994 R2004). Unit: µPa²·s/Hz.

sound field
Region containing sound waves (ANSI S1.1-1994 R2004).

sound intensity
Sound energy flowing through a unit area perpendicular to the direction of propagation per unit time.

sound pressure level (SPL)
The decibel ratio of the time-mean-square sound pressure, in a stated frequency band, to the square of the reference sound pressure (ANSI S1.1-1994 R2004).

For sound in water, the reference sound pressure is one micropascal (p_0 = 1 µPa) and the unit for SPL is dB re 1 µPa²:

$$L_p = 10\log_{10}(p^2/p_0^2) = 20\log_{10}(p/p_0)$$

Unless otherwise stated, SPL refers to the root-mean-square (rms) pressure level. See also 90% sound pressure level and fast-average sound pressure level. Non-rectangular time window functions may be applied during calculation of the rms value, in which case the SPL unit should identify the window type.

sound speed profile
The speed of sound in the water column as a function of depth below the water surface.

source level (SL)
The sound level measured in the far-field and scaled back to a standard reference distance of 1 metre from the acoustic centre of the source. Unit: dB re 1 µPa·m (pressure level) or dB re 1 µPa²·s·m (exposure level).

spectrogram
A visual representation of acoustic amplitude compared with time and frequency.

spectrum
An acoustic signal represented in terms of its power, energy, mean-square sound pressure, or sound exposure distribution with frequency.

temporary threshold shift (TTS)
Temporary loss of hearing sensitivity caused by excessive noise exposure.

transmission loss (TL)
The decibel reduction in sound level between two stated points that results from sound spreading away from an acoustic source subject to the influence of the surrounding environment. Also referred to as propagation loss.

very-high-frequency (HF) cetacean
The functional cetacean hearing group that represents those odontocetes (toothed whales) specialised for very-high-frequency hearing. High-frequency cetaceans from NMFS (2018) are classified as very-high-frequency cetaceans in Southall et al. (2019).

wavelength
Distance over which a wave completes one cycle of oscillation. Unit: metre (m). Symbol: λ.

Appendix A. Acoustic Metrics

A.1. Pressure Related Acoustic Metrics

Underwater sound pressure amplitude is measured in decibels (dB) relative to a fixed reference pressure of p_0 = 1 µPa. Because the perceived loudness of sound, especially pulsed sound such as from seismic airguns, pile driving, and sonar, is not generally proportional to the instantaneous acoustic pressure, several sound level metrics are commonly used to evaluate sound and its effects on marine life. Here we provide specific definitions of relevant metrics used in the accompanying report. Where possible, we follow the American National Standard Institute and International Organization for Standardization definitions and symbols for sound metrics (e.g., ISO 2017, ANSI R2013), but these standards are not always consistent.

The zero-to-peak sound pressure, or peak sound pressure (PK or $L_{p,pk}$; dB re 1 µPa), is the decibel level of the maximum instantaneous acoustic pressure in a stated frequency band attained by an acoustic pressure signal, $p(t)$:

$$L_{p,\text{pk}} = 10\log_{10}\left(\frac{\max|p^2(t)|}{p_0^2}\right) = 20\log_{10}\left(\frac{\max|p(t)|}{p_0}\right) \tag{A-1}$$

PK is often included as a criterion for assessing whether a sound is potentially injurious; however, because it does not account for the duration of an acoustic event, it is generally a poor indicator of perceived loudness.

The peak-to-peak sound pressure (PK-PK or $L_{p,pk\text{-}pk}$; dB re 1 µPa) is the difference between the maximum and minimum instantaneous sound pressure, possibly filtered in a stated frequency band, attained by an impulsive sound, $p(t)$:

$$L_{p,\text{pk-pk}} = 10\log_{10}\left(\frac{[\max(p(t)) - \min(p(t))]^2}{p_0^2}\right) \tag{A-2}$$

The sound pressure level (SPL or L_p; dB re 1 µPa) is the root-mean-square (rms) pressure level in a stated frequency band over a specified time window (T; s). It is important to note that SPL always refers to an rms pressure level and therefore not instantaneous pressure:

$$L_p = 10\log_{10}\left(\frac{1}{T}\int_T g(t)\,p^2(t)\,dt \Big/ p_0^2\right) \tag{A-3}$$

where $g(t)$ is an optional time weighting function. In many cases, the start time of the integration is marched forward in small time steps to produce a time-varying SPL function. For short acoustic events, such as sonar pulses and marine mammal vocalizations, it is important to choose an appropriate time window that matches the duration of the signal. For in-air studies, when evaluating the perceived loudness of sounds with rapid amplitude variations in time, the time weighting function $g(t)$ is often set to a decaying exponential function that emphasizes more recent pressure signals. This function mimics the leaky integration nature of mammalian hearing. For example, human-based fast time-weighted SPL ($L_{p,fast}$) applies an exponential function with time constant 125 ms. A related simpler approach used in underwater acoustics sets $g(t)$ to a boxcar (unity amplitude) function of width 125 ms; the results can be referred to as $L_{p,boxcar\ 125ms}$. Another approach, historically used to evaluate SPL of impulsive signals underwater, defines $g(t)$ as a boxcar function with edges set to the times corresponding to 5% and 95% of the cumulative square pressure function encompassing the duration of an impulsive acoustic event. This calculation is applied individually to each impulse signal, and the results have been referred to as 90% SPL ($L_{p,90\%}$). In this report, SPL refers to $L_{p,boxcar\ 125ms}$.

The sound exposure level (SEL or L_E; dB re 1 µPa²·s) is the time-integral of the squared acoustic pressure over a duration (T):

$$L_E = 10\log_{10}\left(\int_T p^2(t)\,dt \Big/ T_0 p_0^2\right) \quad \text{(A-4)}$$

where T_0 is a reference time interval of 1 s. SEL continues to increase with time when non-zero pressure signals are present. It is a dose-type measurement, so the integration time applied must be carefully considered for its relevance to impact to the exposed recipients.

SEL can be calculated over a fixed duration, such as the time of a single event or a period with multiple acoustic events. When applied to pulsed sounds, SEL can be calculated by summing the SEL of the N individual pulses. For a fixed duration, the square pressure is integrated over the duration of interest. For multiple events, the SEL can be computed by summing (in linear units) the SEL of the N individual events:

$$L_{E,N} = 10\log_{10}\sum_{i=1}^{N} 10^{\frac{L_{E,i}}{10}} \quad \text{(A-5)}$$

Because the SPL and SEL are both computed from the integral of square pressure, these metrics are related numerically by the following expression, which depends only on the duration of the time window T:

$$L_p = L_E - 10\log_{10}(T) \quad \text{(A-6)}$$

When applied, the frequency weighting of an acoustic event should be specified, as in the case of weighted SEL (e.g., *LE,LF,24h*; see Appendix A.4).

A.2. Decidecade Band Analysis

The distribution of a sound's power with frequency is described by the sound's spectrum. The sound spectrum can be split into a series of adjacent frequency bands. Splitting a spectrum into 1 Hz wide bands, called passbands, yields the power spectral density of the sound. This splitting of the spectrum into passbands of a constant width of 1 Hz, however, does not represent how animals perceive sound.

Because animals perceive exponential increases in frequency rather than linear increases, analysing a sound spectrum with passbands that increase exponentially in size better approximates real-world scenarios. In underwater acoustics, a spectrum is commonly split into decidecade bands, which are one tenth of a decade wide. They are approximately one third of an octave (base 2) wide and are therefore often referred to as 1/3-octave-bands. Each octave represents a doubling in sound frequency. The centre frequency of the ith band, $f_c(i)$, is defined as:

$$f_c(i) = 10^{\frac{i}{10}}\,\text{kHz} \quad \text{(A-7)}$$

and the low (f_{lo}) and high (f_{hi}) frequency limits of the ith decade band are defined as:

$$f_{lo,i} = 10^{\frac{-1}{20}} f_c(i) \quad \text{and} \quad f_{hi,i} = 10^{\frac{1}{20}} f_c(i) \quad \text{(A-8)}$$

The decidecade bands become wider with increasing frequency, and on a logarithmic scale the bands appear equally spaced (Figure A-3). The acoustic modelling spans from band 7 (f_c (7) = 5 Hz) to band 44 ($f_c(44)$ = 25 kHz).

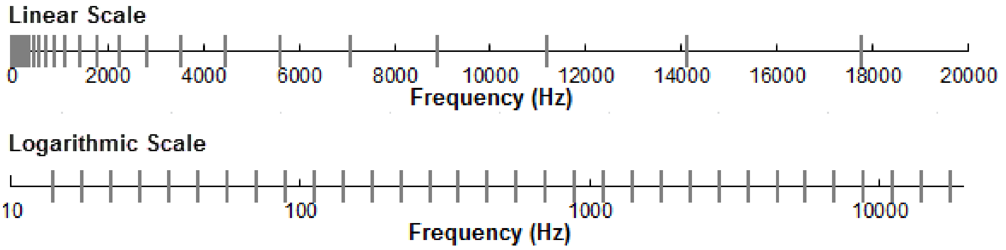

Figure A-1. Decidecade frequency bands (vertical lines) shown on a linear frequency scale and a logarithmic scale.

The sound pressure level in the ith band ($L_{p,i}$) is computed from the spectrum $S(f)$ between $f_{\text{lo},i}$ and $f_{\text{hi},i}$:

$$L_{p,i} = 10 \log_{10} \int_{f_{\text{lo},i}}^{f_{\text{hi},i}} S(f)\, df \qquad \text{(A-9)}$$

Summing the sound pressure level of all the bands yields the broadband sound pressure level:

$$\text{Broadband SPL} = 10 \log_{10} \sum_i 10^{\frac{L_{p,i}}{10}} \qquad \text{(A-10)}$$

Figure A-4 shows an example of how the decidecade band sound pressure levels compare to the sound pressure spectral density levels of an ambient noise signal. Because the decidecade bands are wider with increasing frequency, the decidecade band SPL is higher than the spectral levels at higher frequencies. Acoustic modelling of decidecade bands requires less computation time than 1 Hz bands and still resolves the frequency-dependence of the sound source and the propagation environment.

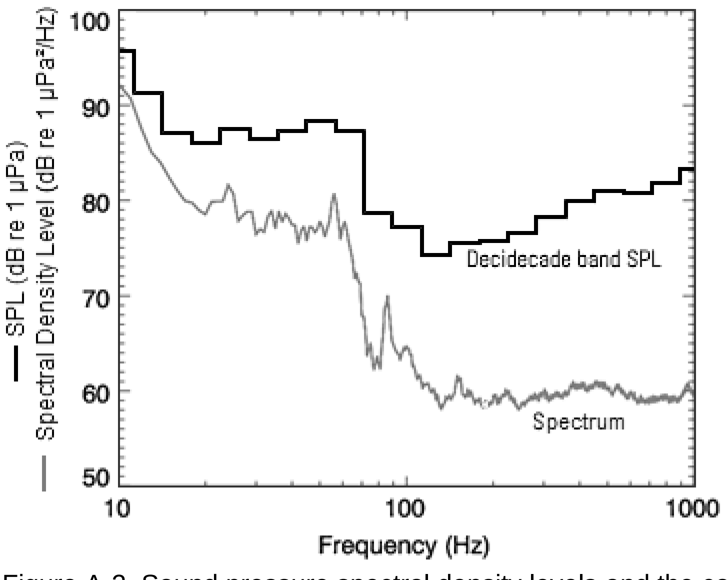

Figure A-2. Sound pressure spectral density levels and the corresponding decidecade band sound pressure levels of example ambient noise shown on a logarithmic frequency scale.

$$f_c(i) = 10^{\frac{i}{10}} \text{ kHz} \qquad \text{(A-11)}$$

and the low (f_{lo}) and high (f_{hi}) frequency limits of the ith decade band are defined as:

$$f_{\text{lo},i} = 10^{\frac{-1}{20}} f_c(i) \quad \text{and} \quad f_{\text{hi},i} = 10^{\frac{1}{20}} f_c(i) \qquad \text{(A-12)}$$

The decidecade bands become wider with increasing frequency, and on a logarithmic scale the bands appear equally spaced (Figure A-3). The acoustic modelling spans from band 7 (f_c (7) = 5 Hz) to band 44 ($f_c(44)$ = 25 kHz).

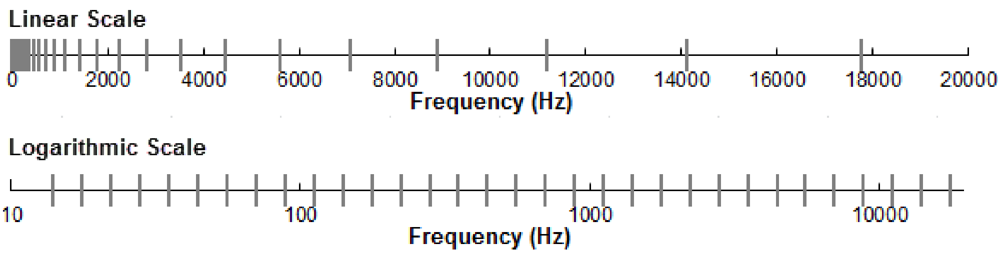

Figure A-3. Decidecade frequency bands (vertical lines) shown on a linear frequency scale and a logarithmic scale.

The sound pressure level in the ith band ($L_{p,i}$) is computed from the spectrum $S(f)$ between $f_{\mathrm{lo},i}$ and $f_{\mathrm{hi},i}$:

$$L_{p,i} = 10 \log_{10} \int_{f_{\mathrm{lo},i}}^{f_{\mathrm{hi},i}} S(f)\, df \tag{A-13}$$

Summing the sound pressure level of all the bands yields the broadband sound pressure level:

$$\text{Broadband SPL} = 10 \log_{10} \sum_i 10^{\frac{L_{p,i}}{10}} \tag{A-14}$$

Figure A-4 shows an example of how the decidecade band sound pressure levels compare to the sound pressure spectral density levels of an ambient noise signal. Because the decidecade bands are wider with increasing frequency, the decidecade band SPL is higher than the spectral levels at higher frequencies. Acoustic modelling of decidecade bands requires less computation time than 1 Hz bands and still resolves the frequency-dependence of the sound source and the propagation environment.

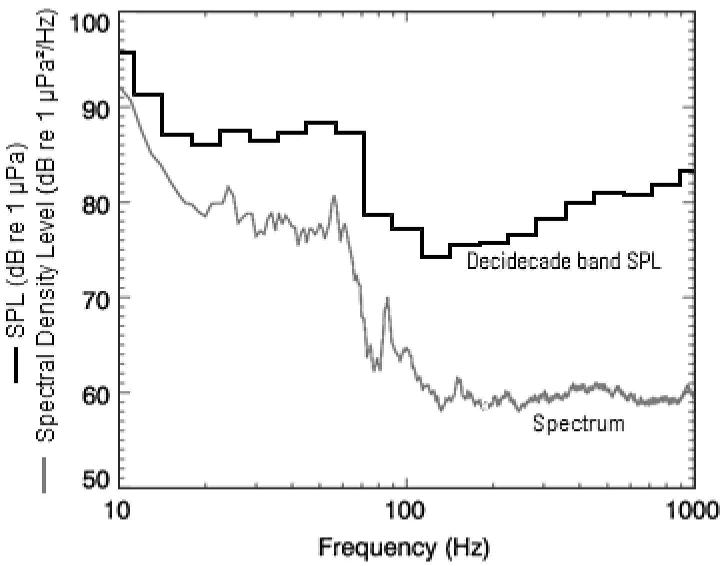

Figure A-4. Sound pressure spectral density levels and the corresponding decidecade band sound pressure levels of example ambient noise shown on a logarithmic frequency scale.

A.3. Marine Mammal Impact Criteria

It has been long recognised that marine mammals can be adversely affected by underwater anthropogenic noise. For example, Payne and Webb (1971) suggested that communication distances of fin whales are reduced by shipping sounds. Subsequently, similar concerns arose regarding effects of other underwater noise sources and the possibility that impulsive sources–primarily airguns used in seismic surveys–could cause auditory injury. This led to a series of workshops held in the late 1990s, conducted to address acoustic mitigation requirements for seismic surveys and other underwater noise sources (NMFS 1998, ONR 1998, Nedwell and Turnpenny 1998, HESS 1999, Ellison and Stein 1999). In the years since these early workshops, a variety of thresholds have been proposed for both injury and disturbance. The following sections summarize the recent development of thresholds; however, this field remains an active research topic.

A.3.1. Auditory Impairment

There are two categories of auditory threshold shifts (also termed Noise Induced Threshold Shift, NITS): Permanent Threshold Shift (PTS), a physical injury to an animal's hearing system; and Temporary Threshold Shift (TTS), a temporary reduction in an animal's hearing sensitivity as the result of physiological and mechanical processes in the inner ear. While PTS undoubtedly constitutes an injury, TTS (as a temporary effect) was not considered in the same way. However, recent research clearly indicates that already moderate levels (<12 dB) of TTS produced an accelerated hearing loss (PTS) resulting from progressive neural degeneration with age (Kujawa and Liberman 2006, 2009, Maison et al. 2013, Kujawa and Liberman 2015).

The most recent criteria for assessing possible effects of impulsive sounds (such as pile driving or seismic impulses) noise and non-impulsive sound (such as vessel noise) on marine mammals, Southall et al. (2019), was applied in this study.

A.3.2. Behavioural response

Numerous studies on marine mammal behavioural responses to sound exposure have not resulted in consensus in the scientific community regarding the appropriate metric for assessing behavioural reactions. However, it is recognised that the context in which the sound is received affects the nature and extent of responses to a stimulus (Southall et al. 2007, Ellison and Frankel 2012, Southall et al. 2016).

For impulsive noise, NMFS currently uses step function thresholds of 160 dB re 1 µPa SPL (unweighted) to assess and regulate noise-induced behavioural impacts for marine mammals (NOAA 2018, NOAA 2019). The threshold for impulsive sound is derived from the High-Energy Seismic Survey (HESS) panel (HESS 1999) report that, in turn, is based on the responses of migrating mysticete whales to airgun sounds (Malme et al. 1984). The HESS team recognised that behavioural responses to sound may occur at lower levels, but significant responses were only likely to occur above a SPL of 140 dB re 1 µPa. Southall et al. (2007) found varying responses for most marine mammals between a SPL of 140 and 180 dB re 1 µPa, consistent with the HESS (1999) report, but lack of convergence in the data prevented them from suggesting explicit step functions.

A.4. Marine Mammal Frequency Weighting

The potential for noise to affect animals depends on how well the animals can hear it. Noises are less likely to disturb or injure an animal if they are at frequencies that the animal cannot hear well. An exception occurs when the sound pressure is so high that it can physically injure an animal by non-auditory means (i.e., barotrauma). For sound levels below such extremes, the importance of sound components at particular frequencies can be scaled by frequency weighting relevant to an animal's sensitivity to those frequencies (Nedwell and Turnpenny 1998, Nedwell et al. 2007).

A.4.1. Marine mammal frequency weighting functions

In 2015, a U.S. Navy technical report by Finneran (2015) recommended new auditory weighting functions. The overall shape of the auditory weighting functions is similar to human A-weighting functions, which follows the sensitivity of the human ear at low sound levels. The new frequency-weighting function is expressed as:

$$G(f) = K + 10\log_{10}\left[\left(\frac{(f/f_{lo})^{2a}}{\left[1+(f/f_{lo})^2\right]^a\left[1+(f/f_{hi})^2\right]^b}\right)\right] \tag{A-15}$$

Finneran (2015) proposed five functional hearing groups for marine mammals in water: low-, mid-, and high-frequency cetaceans, phocid pinnipeds, and otariid pinnipeds. The parameters for these frequency-weighting functions were further modified the following year (Finneran 2016) and were adopted in NOAA's technical guidance that assesses noise impacts on marine mammals (NMFS 2016, NMFS 2018). Mid-frequency cetaceans from NMFS (2018) are classified as high-frequency cetaceans in Southall et al. (2019), and high-frequency cetaceans from NMFS (2018) are classified as very-high-frequency cetaceans, but the weighting functions remain the same. Table A-1 lists the frequency-weighting parameters for each hearing group; Figure A-5 shows the resulting frequency-weighting curves.

Table A-1. Parameters for the auditory weighting functions used in this project as recommended by Southall et al. (2019).

Hearing group	a	b	f_{lo} (Hz)	f_{hi} (kHz)	K (dB)
Low-frequency cetaceans (baleen whales)	1.0	2	200	19,000	0.13
High-frequency cetaceans (dolphins, plus toothed, beaked, and bottlenose whales)	1.6	2	8,800	110,000	1.20
Very-high-frequency cetaceans (true porpoises, *Kogia*, river dolphins, cephalorhynchid, *Lagenorhynchus cruciger* and *L. australis*)	1.8	2	12,000	140,000	1.36

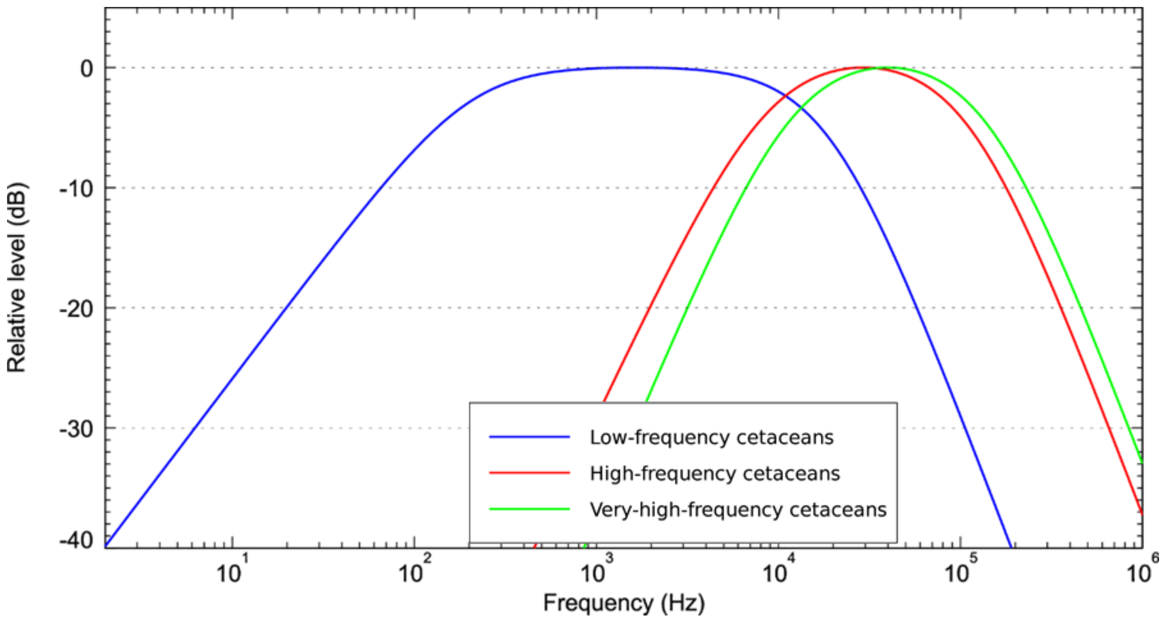

Figure A-5. Auditory weighting functions for functional marine mammal hearing groups as recommended by Southall et al. (2019).

Appendix B. VSP Source

B.1. Airgun Array Source Model

The source levels and directivity of the seismic source were predicted with JASCO's Airgun Array Source Model (AASM). AASM includes low- and high-frequency modules for predicting different components of the seismic source spectrum. The low-frequency module is based on the physics of oscillation and radiation of airgun bubbles, as originally described by Ziolkowski (1970), that solves the set of parallel differential equations that govern bubble oscillations. Physical effects accounted for in the simulation include pressure interactions between airguns, port throttling, bubble damping, and generator-injector (GI) gun behaviour discussed by Dragoset (1984), Laws et al. (1990), and Landrø (1992). A global optimisation algorithm tunes free parameters in the model to a large library of airgun source signatures.

While airgun signatures are highly repeatable at the low frequencies, which are used for seismic imaging, their sound emissions have a large random component at higher frequencies that cannot be predicted using a deterministic model. Therefore, AASM uses a stochastic simulation to predict the high-frequency (800−25,000 Hz) sound emissions of individual airguns, using a data-driven multiple-regression model. The multiple-regression model is based on a statistical analysis of a large collection of high quality seismic source signature data recently obtained from the Joint Industry Program (JIP) on Sound and Marine Life (Mattsson and Jenkerson 2008). The stochastic model uses a Monte-Carlo simulation to simulate the random component of the high-frequency spectrum of each airgun in an array. The mean high-frequency spectra from the stochastic model augment the low-frequency signatures from the physical model, allowing AASM to predict airgun source levels at frequencies up to 25,000 Hz.

AASM produces a set of "notional" signatures for each array element based on:

- Array layout
- Volume, operating depth, and firing pressure of each airgun
- Interactions between different airguns in the array

These notional signatures are the pressure waveforms of the individual airguns at a standard reference distance of 1 m; they account for the interactions with the other airguns in the array. The signatures are summed with the appropriate phase delays to obtain the far-field source signature of the entire array in all directions. This far-field array signature is filtered into 1/3-octave-bands to compute the source levels of the array as a function of frequency band and azimuthal angle in the horizontal plane (at the source depth), after which it is considered a directional point source in the far field.

A seismic array consists of many sources and the point source assumption is invalid in the near field where the array elements add incoherently. The maximum extent of the near field of an array (R_{nf}) is:

$$R_{\mathrm{nf}} < \frac{l^2}{4\lambda} \quad \text{(B-1)}$$

where λ is the sound wavelength and l is the longest dimension of the array (Lurton 2002, §5.2.4). For example, a seismic source length of l = 21 m yields a near-field range of 147 m at 2 kHz and 7 m at 100 Hz. Beyond this R_{nf} range, the array is assumed to radiate like a directional point source and is treated as such for propagation modelling.

The interactions between individual elements of the array create directionality in the overall acoustic emission. Generally, this directionality is prominent mainly at frequencies in the mid-range between tens of hertz to several hundred hertz. At lower frequencies, with acoustic wavelengths much larger than the inter-airgun separation distances, the directionality is small. At higher frequencies, the pattern of lobes is too finely spaced to be resolved and the effective directivity is less.

B.2. VSP Source Parameters

The layout of the seismic source is provided in Figure D-1. Details of the airgun parameters are provided in Table B-1. The right panel of Figure D-1 should the layout of the array with depth and offset, in the context of this source geometry the broadside direction is perpendicular to the sagittal plane of the array and the endfire direction is parallel to the sagittal plane of the array.

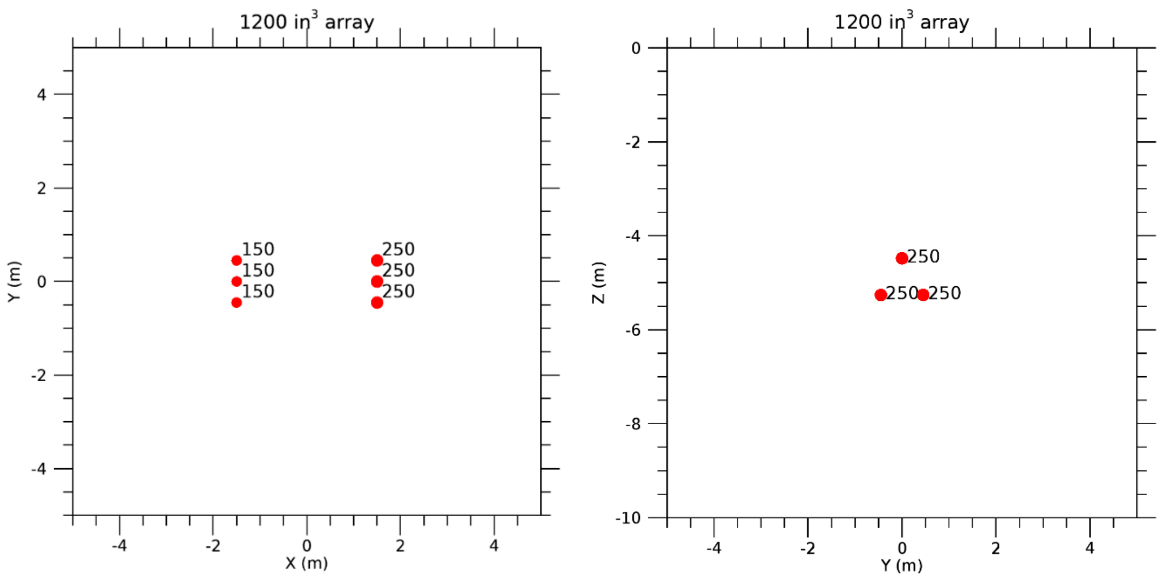

Figure B-1. Layout in plan view (left) and cross-section view (right) of the modelled 1200 in^3 VSP source array. Operational depth is 5 m. The labels indicate the firing volume (in cubic inches) for each airgun. Also see Table B-1.

Table B-1. Layout of the modelled 1200 in^3 seismic source array. Operational depth is 5 m. Firing pressure for all guns is 2000 psi. Also see Figure B-1.

Gun	x (m)	y (m)	z (m)	Volume (in^3)
1	1.5	0	4.48	250
2	1.5	-0.45	5.26	250
3	1.5	0.45	5.26	250
4	-1.5	0	4.48	150
5	-1.5	-0.45	5.26	150
6	-1.5	0.45	5.26	150

B.3. Array Source Levels and Directivity

Figure B-2 shows the broadside (perpendicular to the sagittal plane), endfire (parallel to the sagittal plane), and vertical overpressure signature and corresponding power spectrum levels for the 1200 in^3 array (Appendix B.2). Horizontal decidecade-band source levels shown as a function of band centre frequency and azimuth (Figure B-3) indicate that this array is mainly isotropic.

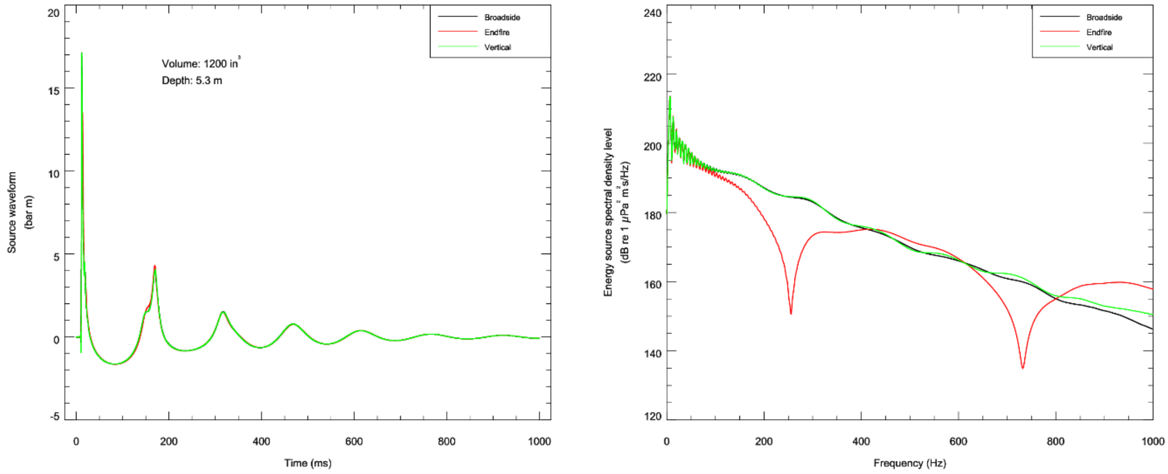

Figure B-2. Predicted source level details for the 1200 in^3 array at a 5 m operational depth.(Left) the overpressure signature and (right) the power spectrum for in-plane horizontal (broadside), perpendicular (endfire), and vertical directions.

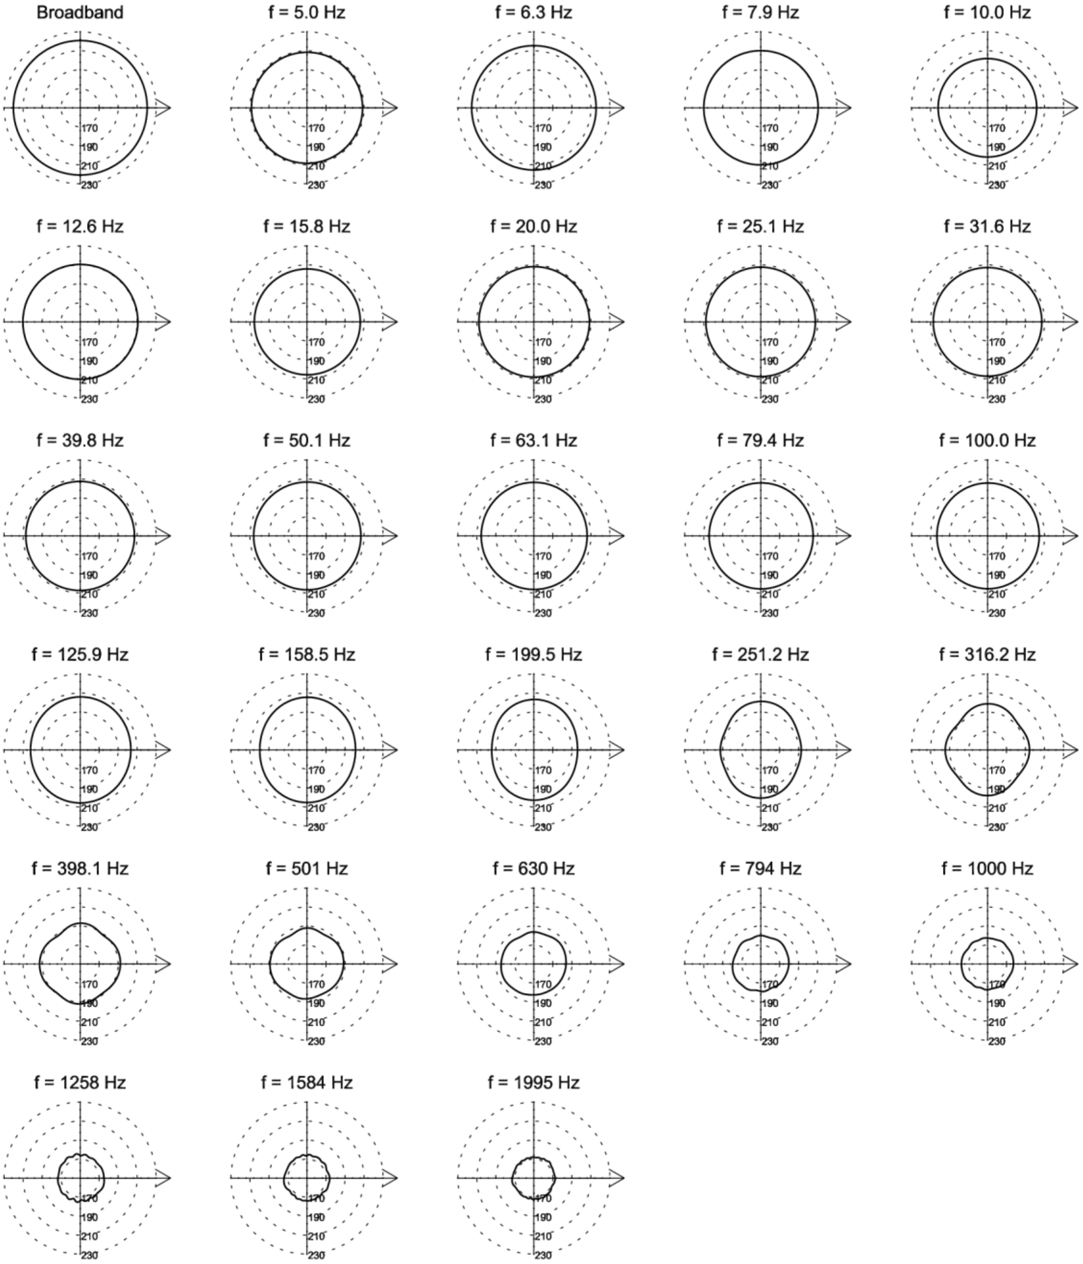

Figure B-3. Directionality of the predicted horizontal source levels for the 1200 in^3 seismic source array, 5 Hz to 2 kHz. Source levels (in dB re 1 $\mu Pa^2 \cdot s\ m^2$) are shown as a function of azimuth for the centre frequencies of the decidecade-bands modelled; frequencies are shown above the plots. The endfire axis is to the right. Operational depth is 5 m.

Appendix C. Sound Propagation Models

C.1. Transmission Loss

The propagation of sound through the environment was modelled by predicting the acoustic transmission loss–a measure, in decibels, of the decrease in sound level between a source and a receiver some distance away. Geometric spreading of acoustic waves is the predominant way by which transmission loss occurs. Transmission loss also happens when the sound is absorbed and scattered by the seawater, and absorbed scattered, and reflected at the water surface and within the seabed. Transmission loss depends on the acoustic properties of the ocean and seabed, its value changes with frequency.

If the acoustic source level (SL), expressed in dB re 1 µPa^{2}m^2, and transmission loss (TL), in units of dB, at a given frequency are known, then the received level (RL) at a receiver location can be calculated in dB re 1 µPa by:

$$\mathrm{RL} = \mathrm{SL} - \mathrm{TL} \tag{C-1}$$

C.2. Noise Propagation with FWRAM

For impulsive sounds from the seismic source, time-domain representations of the pressure waves generated in the water are required to calculate SPL and PK. Furthermore, the seismic source must be represented as a distributed source to accurately characterise vertical directivity effects in the near-field zone. For this study, synthetic pressure waveforms were computed using FWRAM, which is a time-domain acoustic model based on the same wide-angle parabolic equation (PE) algorithm as MONM. FWRAM computes synthetic pressure waveforms versus range and depth for range-varying marine acoustic environments, and it takes the same environmental inputs as MONM (bathymetry, water sound speed profile, and seafloor geoacoustic profile). Unlike MONM, FWRAM computes pressure waveforms via Fourier synthesis of the modelled acoustic transfer function in closely spaced frequency bands. FWRAM employs the array starter method to accurately model sound propagation from a spatially distributed source (MacGillivray and Chapman 2012).

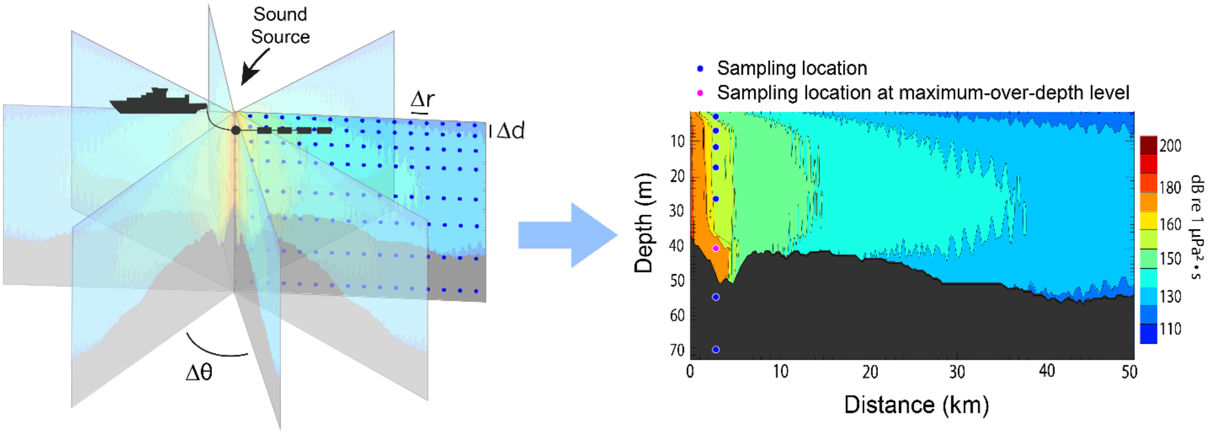
Besides providing direct calculations of the PK and SPL, the synthetic waveforms from FWRAM can also be used to convert the SEL values from MONM to SPL.

C.3. MONM-BELLHOP

Long-range sound fields were computed using JASCO's Marine Operations Noise Model (MONM). Compared to VSTACK, MONM less accurately predicts steep-angle propagation for environments with higher shear speed but is well suited for effective longer-range estimation. This model computes sound propagation at frequencies of 10 Hz to 1.6 kHz via a wide-angle parabolic equation solution to the acoustic wave equation (Collins 1993) based on a version of the U.S. Naval Research Laboratory's Range-dependent Acoustic Model (RAM), which has been modified to account for a solid seabed (Zhang and Tindle 1995). MONM computes sound propagation at frequencies > 1.6 kHz via the BELLHOP Gaussian beam acoustic ray-trace model (Porter and Liu 1994).

The parabolic equation method has been extensively benchmarked and is widely employed in the underwater acoustics community (Collins et al. 1996). MONM accounts for the additional reflection loss at the seabed, which results from partial conversion of incident compressional waves to shear waves at the seabed and sub-bottom interfaces, and it includes wave attenuations in all layers. MONM incorporates the following site-specific environmental properties: a bathymetric grid of the modelled area, underwater sound speed as a function of depth, and a geoacoustic profile based on the overall stratified composition of the seafloor.

MONM computes acoustic fields in three dimensions by modelling transmission loss within two-dimensional (2-D) vertical planes aligned along radials covering a 360° swath from the source, an approach commonly referred to as N×2-D. These vertical radial planes are separated by an angular step size of $\Delta\theta$, yielding N = 360°/$\Delta\theta$ number of planes.



MONM treats frequency dependence by computing acoustic transmission loss at the centre frequencies of decidecade bands. Sufficiently many frequency bands, starting at 5 Hz, are modelled to include most of the acoustic energy emitted by the source. At each centre frequency, the transmission loss is modelled within each of the N vertical planes as a function of depth and range from the source. The decidecade-band received per-pulse SEL are computed by subtracting the band transmission loss values from the directional source level in that frequency band. Composite broadband received per-pulse SEL are then computed by summing the received decidecade-band levels.

The received per-pulse SEL sound field within each vertical radial plane is sampled at various ranges from the source, generally with a fixed radial step size. At each sampling range along the surface, the sound field is sampled at various depths, with the step size between samples increasing with depth below the surface. The step sizes are chosen to provide increased coverage near the depth of the source and at depths of interest in terms of the sound speed profile. For areas with deep water, sampling is not performed at depths beyond those reachable by marine mammals. The received per-pulse SEL at a surface sampling location is taken as the maximum value that occurs over all samples within the water column, i.e., the maximum-over-depth received per-pulse SEL. These maximum-over-depth per-pulse SEL are presented as colour contours around the source.

C.4. Wavenumber Integration Model

Sound pressure levels near the seismic source were modelled using JASCO's VSTACK wavenumber integration model. VSTACK computes synthetic pressure waveforms versus depth and range for arbitrarily layered, range-independent acoustic environments using the wavenumber integration approach to solve the exact (range-independent) acoustic wave equation. This model is valid over the full angular range of the wave equation and can fully account for the elasto-acoustic properties of the sub-bottom. Wavenumber integration methods are extensively used in the field of underwater acoustics and seismology where they are often referred to as reflectivity methods or discrete wavenumber methods. VSTACK computes sound propagation in arbitrarily stratified water and seabed layers by decomposing the outgoing field into a continuum of outward-propagating plane cylindrical waves. Seabed reflectivity in the model is dependent on the seabed layer properties: compressional and shear wave speeds, attenuation coefficients, and layer densities. The output of the model can be post-processed to yield estimates of the SEL, SPL, and PK.

VSTACK accurately predicts steep-angle propagation in the proximity of the source, but it is computationally slow at predicting sound pressures at large distances due to the need for smaller wavenumber steps with increasing distance. Additionally, VSTACK assumes range-invariant bathymetry with a horizontally stratified medium (i.e., a range-independent environment) which is azimuthally symmetric about the source. VSTACK is thus best suited to modelling the sound field near the source.

Appendix D. Methods and Parameters

This section describes the specifications of the seismic source that was used at all sites and the environmental parameters used in the propagation models.

D.1. Estimating Range to Thresholds Levels

Sound level contours were calculated based on the underwater sound fields predicted by the propagation models, sampled by taking the maximum value over all modelled depths above the sea floor for each location in the modelled region. The predicted distances to specific levels were computed from these contours. Two distances relative to the source are reported for each sound level: 1) R_{max}, the maximum range to the given sound level over all azimuths, and 2) $R_{95\%}$, the range to the given sound level after the 5% farthest points were excluded (see examples in Figure D-1).

The $R_{95\%}$ is used because sound field footprints are often irregular in shape. In some cases, a sound level contour might have small protrusions or anomalous isolated fringes. This is demonstrated in the image in Figure D-1(a). In cases such as this, where relatively few points are excluded in any given direction, R_{max} can misrepresent the area of the region exposed to such effects, and $R_{95\%}$ is considered more representative. In strongly asymmetric cases such as shown in Figure D-1(b), on the other hand, $R_{95\%}$ neglects to account for significant protrusions in the footprint. In such cases R_{max} might better represent the region of effect in specific directions. Cases such as this are usually associated with bathymetric features affecting propagation. The difference between R_{max} and $R_{95\%}$ depends on the source directivity and the non-uniformity of the acoustic environment.

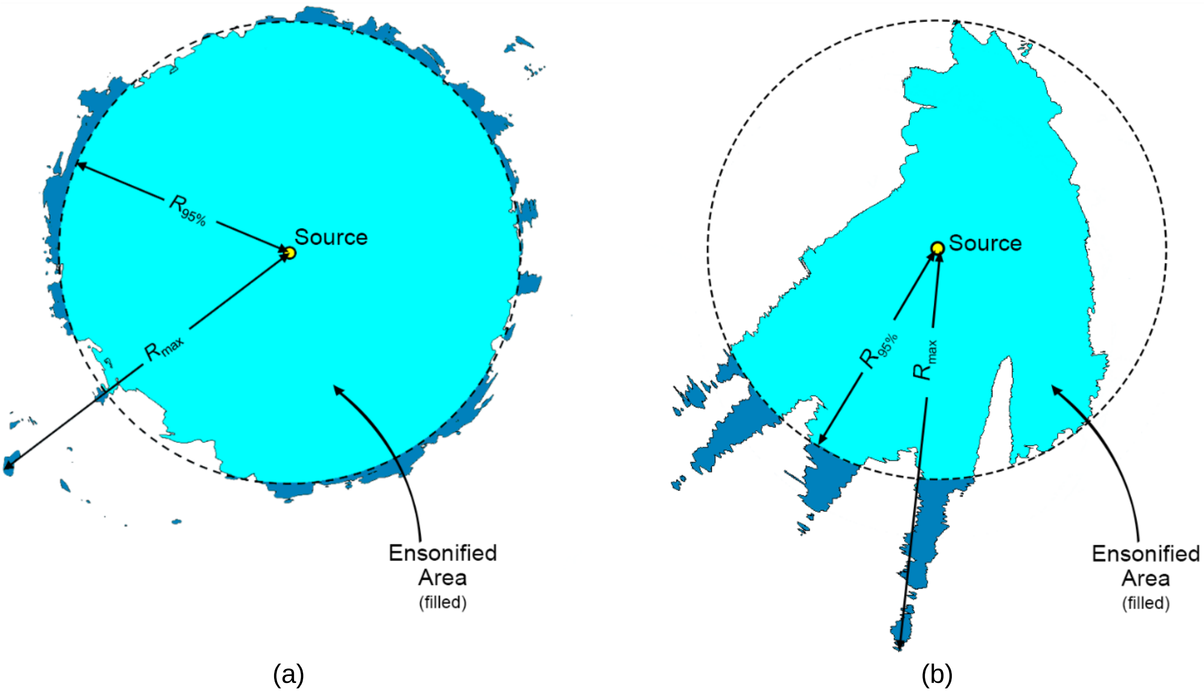


Figure D-1. Sample areas ensonified to an arbitrary sound level with R_{max} and $R_{95\%}$ ranges shown for two different scenarios. (a) Largely symmetric sound level contour with small protrusions. (b) Strongly asymmetric sound level contour with long protrusions. Light blue indicates the ensonified areas bounded by $R_{95\%}$; darker blue indicates the areas outside this boundary which determine R_{max}.

D.2. Estimating SPL from Modelled SEL Results

The per-pulse SEL of sound pulses is an energy-like metric related to the dose of sound received over a pulse's entire duration. The pulse SPL on the other hand, is related to its intensity over a specified time interval. Seismic pulses typically lengthen in duration as they propagate away from their source, due to seafloor and surface reflections, and other waveguide dispersion effects. The changes in pulse length, and therefore the time window considered, affect the numeric relationship between SPL and SEL. This study has applied a fixed window duration to calculate SPL (T_{fix} = 125 ms; see Appendix A.1), as implemented in Martin et al. (2017b). Full-waveform modelling was used to estimate SPL, but this type of modelling is computationally intensive, and can be prohibitively time consuming when run at high spatial resolution over large areas.

For the current study, FWRAM (Appendix C.2) was used to model synthetic seismic pulses over the frequency range 5–1024 Hz. This was performed along all broadside and endfire radials at modelled site 1. FWRAM uses Fourier synthesis to recreate the signal in the time domain so that both the SEL and SPL from the source can be calculated. A 125 ms fixed time window positioned to maximise the SPL over the pulse duration was applied. The resulting SEL-to-SPL offsets were averaged in 0.01 km range bins along each modelled radial and depth, and the 90th percentile was selected at each range to generate a generalised range-dependent conversion function for the site. The range-dependent conversion function was then applied to predicted per-pulse SEL results from MONM to model and map SPL values. Figure D-2 shows the conversion offsets for the WHP site; the spatial variation is caused by changes in the received airgun pulse as it propagates from the source

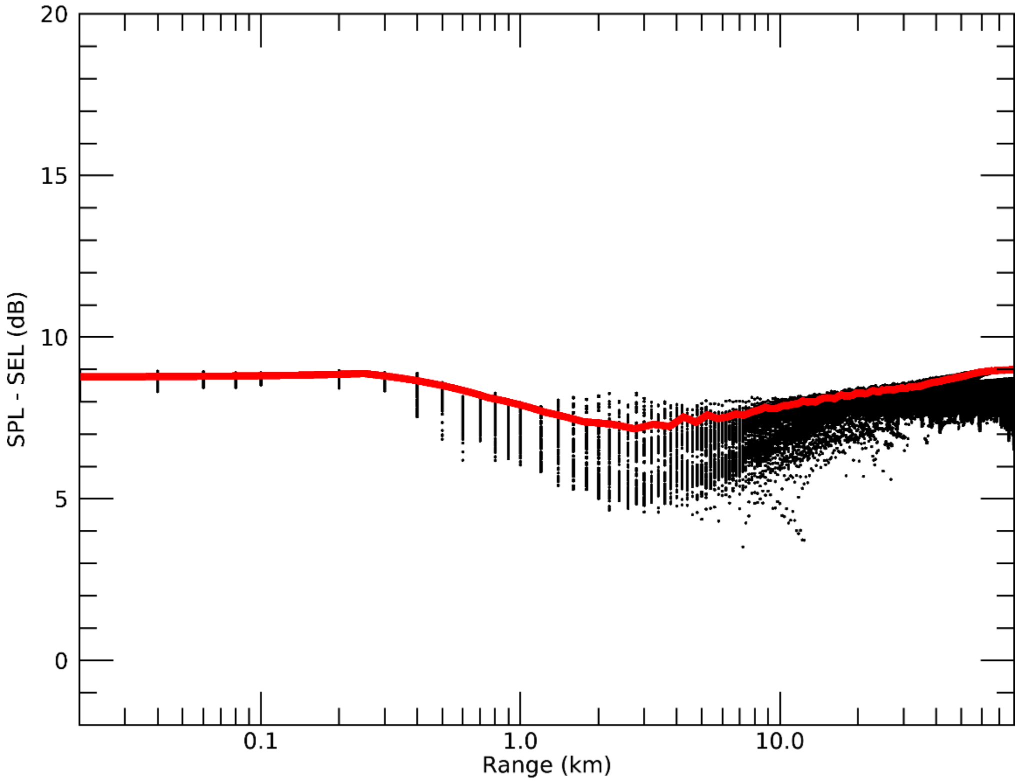

Figure D-2. Range-and-depth-dependent conversion offsets for converting SEL to SPL for VSP pulses at the Dorado WHP site. Black dots are the modelled differences between SEL and SPL across different radials and receiver depths; the solid red line is the 90th percentile of the modelled differences at each range.

D.3. Accumulated SEL Calculation

When there are many seismic pulses, it becomes computationally prohibitive to perform sound propagation modelling for every single event. The distance between the consecutive seismic impulses is small enough, however, that the environmental parameters that influence sound propagation are virtually the same for many impulse points. The acoustic fields can, therefore, be modelled for a subset of seismic pulses and estimated at several adjacent ones. After sound fields from representative impulse location(s) are calculated, they are adjusted to account for the source position for nearby impulses.

Although estimating the cumulative sound field with the described approach is not as precise as modelling sound propagation at every impulse location, small-scale, site-specific sound propagation features tend to blur and become less relevant when sound fields from adjacent impulses are summed. Larger scale sound propagation features, primarily dependent on water depth, dominate the cumulative field. The accuracy of the present method acceptably reflects those large-scale features, thus providing a meaningful estimate of a wide area SEL field in a computationally feasible framework.

To produce the map of accumulated received sound level distributions and calculate distances to specified sound level thresholds, the maximum-over-depth level was calculated at the single impulse modelled site(s) within the modelled region. The radial grids of maximum-over-depth and seafloor sound levels for each impulse were then resampled (by linear triangulation) to produce a regular Cartesian grid. The sound field grids from all impulses were summed (Equation A-5) to produce the cumulative sound field grid with cell sizes of 20 m. The contours and threshold ranges were calculated from these flat Cartesian projections of the modelled acoustic fields. The single-impulse SEL fields were computed over model grids approximately 80 × 80 km in range, which encompasses the full area of the cumulative grid (the entire survey area).

D.4. Environmental Parameters

D.4.1. Bathymetry

Water depths throughout the modelled areas were extracted from a dataset provided by the client (Berry 2019) and these data were re-gridded from several overlapping sub dataset using bathymetry acquired during recent surveys in the area of the dorado development project. The Australian Bathymetry and Topography Grid, a 9 arc-second grid data (Whiteway 2009) was used as a base layer for re-gridding. Bathymetry data were re-gridded onto a Map Grid of Australia (MGA) coordinate projection (Zone 54) with a regular grid spacing of 100 × 100 m. For large the scale overview inset maps in the report, Australian Bathymetry and Topography Grid, a 9 arc-second grid data (Whiteway 2009) was used to supplement client supplied data.

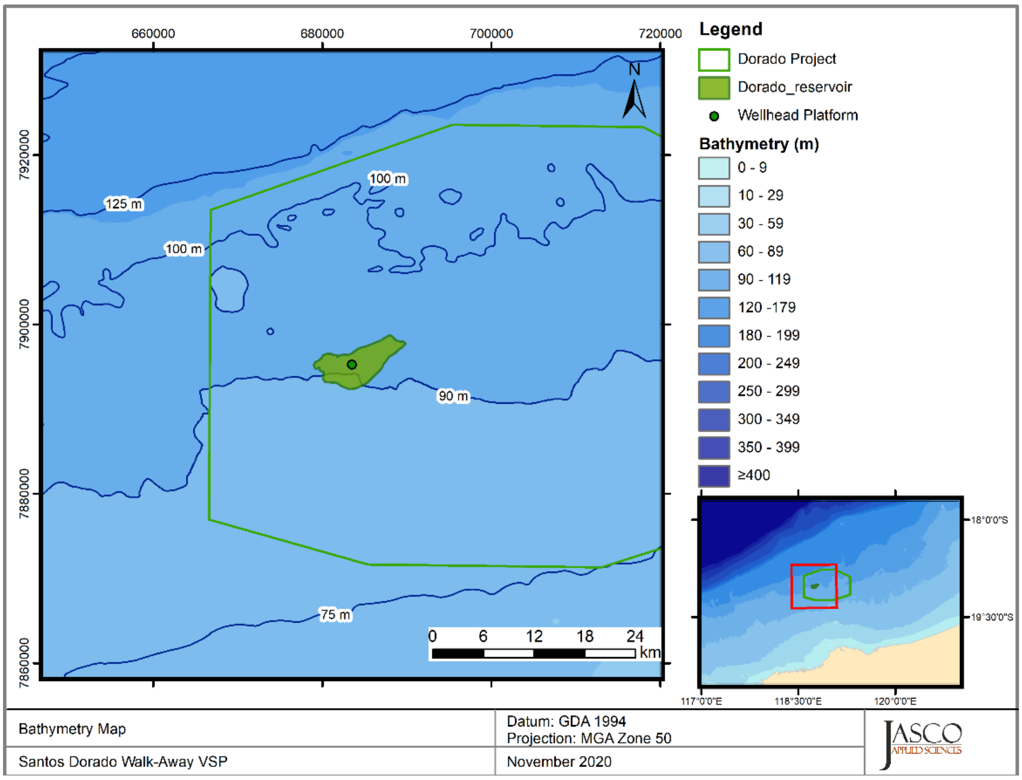

Figure D-3. Bathymetry in the modelled area.

D.4.2. Sound speed profile

The sound speed profile in the area was derived from temperature and salinity profiles from the U.S. Naval Oceanographic Office's *Generalized Digital Environmental Model V 3.0* (GDEM; Teague et al. 1990, Carnes 2009). GDEM provides an ocean climatology of temperature and salinity for the world's oceans on a latitude-longitude grid with 0.25° resolution, with a temporal resolution of one month, based on global historical observations from the U.S. Navy's Master Oceanographic Observational Data Set (MOODS). The climatology profiles include 78 fixed depth points to a maximum depth of 6800 m (where the ocean is that deep). The GDEM temperature-salinity profiles were converted to sound speed profiles according to Coppens (1981).

Mean monthly sound speed profiles were derived from the GDEM profiles within a 100 km box radius encompassing all modelled sites. The July sound speed profile is expected to be most favourable to longer-range sound propagation during the proposed survey time frame. As such, July was selected for sound propagation modelling to ensure precautionary estimates of distances to received sound level thresholds. Figure D-4 shows the resulting profile used as input to the sound propagation modelling.

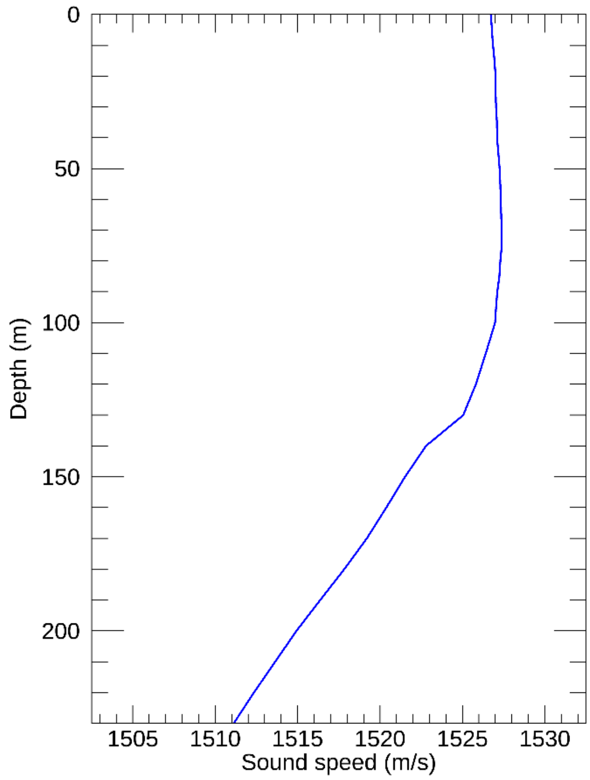

Figure D-4. The modelling sound speed profile corresponding to July Profiles are calculated from temperature and salinity profiles from *Generalized Digital Environmental Model* V 3.0 (GDEM; Teague et al. 1990, Carnes 2009).

D.4.3. Geoacoustics

For the modelled sites the seabed in the area has been described as a calcarenite substrate overlain with a layer of sand (NGI 2017). This is very similar to a profile described in association with measurement data (McCauley et al. 2016), and other modelling studies in the region (AIMS 2018). The geoacoustic parameters used for modelling (Table D-1) are based on Duncan et al. (2009).

Table D-1. Geoacoustic profile for the modelled site

Depth below seafloor (m)	Predicted lithology	Density (g/cm³)	Compressional wave		Shear wave	
			Speed (m/s)	Attenuation (dB/λ)	Speed (m/s)	Attenuation (dB/λ)
0–10	Medium carbonate sand	1.8	1700	0.8	350	2.5
>10	Calcarenite	2.4	2800	0.1		

D.5. Model Validation Information

Predictions from JASCO's propagation models (MONM, FWRAM, and VSTACK) have been validated against experimental data from a number of underwater acoustic measurement programs conducted by JASCO globally, including the United States and Canadian Artic, Canadian and southern United States waters, Greenland, Russia and Australia (Hannay and Racca 2005, Aerts et al. 2008, Funk et al. 2008, Ireland et al. 2009, O'Neill et al. 2010, Warner et al. 2010, Racca et al. 2012a, Racca et al. 2012b, Matthews and MacGillivray 2013, Martin et al. 2015, Racca et al. 2015, Martin et al. 2017a, Martin et al. 2017b, Warner et al. 2017, MacGillivray 2018, McPherson et al. 2018, McPherson and Martin 2018).

In addition, JASCO has conducted measurement programs associated with a significant number of anthropogenic activities which have included internal validation of the modelling (including McCrodan et al. 2011, Austin and Warner 2012, McPherson and Warner 2012, Austin and Bailey 2013, Austin et al. 2013, Zykov and MacDonnell 2013, Austin 2014, Austin et al. 2015, Austin and Li 2016, Martin and Popper 2016).
